expressed great doubt as to the value of serumtherapy, especially that of antistreptococcic serum, and of internal antisepsis in general.

Dr. Lejars of Paris said that this question of the treatment of infected areas was essentially one of practice; that no theoretical doctrine should be at all considered. In recent years the treatment of infected areas has served as a theme for numerous experimental and bacteriological researches. The problem being complex it is necessary to study it from different sides: (1) Recently infected areas where the infection as yet remains local, or better, perhaps, recent wounds supposed to be infected. This presumption ought to be extended to every accidental wound, because as a matter of fact surgical wounds themselves are far from being free from microbes. Moreover, we have no means or recognizing in a recent wound whether the microorganisms are virulent or not. Therefore every accidental wound at least ought to be treated as an infected one. Now, what shall be the treatment? The primary thing is mechanically to clean the wound as well as possible, but to respect the integrity of living cells that they can aid us by their reaction of defense. To accomplish this cleansing, sterile water with sterile sponges is the best, though it is not always the nature of the liquid employed so much as the manner of its employment that gives the results. Antiseptic solutions sufficiently diluted so as not to injure the cells of the part have no better effect than sterile water. The dressing should be aseptic, absorbent, protective, and should immobilize the part in a manner applicable to different regions, and for a variable time. (2) Infected areas where the infection is evidenced by local or general reactions more or less marked. Here also two possibilities must be borne in mind, recent infection without suppuration and with suppuration well developed. In either case specific serumtherapy is indicated. This is the natural scientific method, and is the principal one of the future. Unfortunately, it has not yet reached anything like perfection. We possess now only the antitetanic and the antistreptococcic sera; the former has furnished results only sufficient to entitle it preventive, the second is limited in its application. In certain cases of putrid suppuration or gangrene, oxygenated water, which seems to have a powerful effect on anaerobic organisms, will be a valuable resource, the efficaciousness of which has been proven. (3) Infected sites accompanied by severe general symptoms, traumatic septicemia. In this again specific serumtherapy should be employed. But local treatment, which should be rational in accordance with the preceding principles, should not be neglected. Moreover, the natural resistance of the body should be enhanced.

Surgery of the Lung.—Dr. Murphy of Chicago said that the day had passed when the chest was to be treated differently, as to its surgical aspect, from any other cavity in the body. For years it has been an axiom to open up an abscess wherever it might be, even in the brain; yet the surgeon stopped at the lung and dared not enter. He claimed what all surgeons feared was collapse of the lung when the chest was opened, but from experiments on animals he has proved that this is easily avoided. The principal factor in respiration is the creation of the vacuum by the movement of the diaphragm downward; now when the right chest is opened, this vacuum on the left side instead of causing the left lung to expand, brings about a deflection of the mediastinum toward the left side causing collapse of the left lung. The speaker said if the mediastinum toward the left side causing collapse of tion, the collapse would not take place, making the operation a perfectly safe one. He advocated therefore that the lung be treated surgically the same as any other organ.

Ligation of Aorta.—Dr. W. W. Keen of Philadelphia reported a case in which this operation was performed for an aneurism of the abdominal aorta. The ligation was made just below the diaphragm. The patient made a good recovery from the operative procedure itself, being up and around the ward. The aneurism began again to pulsate, probably from reestablished collateral circulation. Forty-eight days after the operation the patient died. The autopsy showed an ulceration of the aorta, due to the ligature, and secondary hemorrhage. Dr. Keen reviewed the twelve other reported cases. In all death had supervened by reason of secondary hemorrhage or direct operative causes. The tugging at the elastic wall of the aorta probably induces the ulceration. Murray's method of preliminary aortic compression is worthy of consideration.

FIFTH DAY—AUGUST 7TH.

Gastrointestinal Anastomoses.—This subject was discussed by a large number of surgeons. The first report was made by Prof. Roux of Lausanne. Experimentation on dogs does not give a true idea of the operation on man. As to the operation, lateral anastomosis is the most practical. Intestinal anastomosis is contraindicated when the state of the patient is such as to permit only an enterostomy. It is to be done in the case of numerous adhesions when it offers greater chances. It is the operation of choice in inoperable tumors and in certain cases of inflammation when the inflammatory foci (as actinomycosis) are multiple and inaccessible. Gastrointestinal anastomosis precedes pylorectomy as a preliminary operation if the condition of the patient renders it at all necessary. It replaces pylorectomy if the tumor is inoperable. In order to give the patient the benefit of a radical operation when possible, or a complete palliative one if a relapse of the tumor should occur, the new pylorus should be made as far away as possible from the old one. In non-cancerous affections of the pylorus and the stomach on account of which a new pylorus is desirable, gastroenteros-

tomy is preferable to pylorectomy and pyloroplasty because it is easier and as efficacious. To a good operator suture is preferable to any instrumental contrivance. Still the Murphy button, the best of the automatic couplers, finds a favorable place in these cases, where minutes are to be counted.

Dr. Souligoux of Paris said that intestinal anastomosis constitutes the principal or at least the complementary operation in all cases of cancer or stricture of the intestine. In case of acute intestinal obstruction the intestinal anastomosis ought to be secondary to the preliminary creation of an artificial anus. In a case of an adherent tumor, or one the removal of which would complicate seriously the operation, the only thing to do is intestinal anastomosis. Lateral anastomosis is always more simple, rapid and sure than circular entororraphy. In cicatricial stenosis of the pylorus or of the first part of the duodenum gastroenterostomy is the operation of choice, since it is almost without danger and since by it the patient may return to an excellent state of health. In stenosis of cancerous origin it is also most often employed, though pylorectomy is to be preferred in those cases where the cancer is only beginning, and is not attached to the liver, pancreas, colon, or preaortic ganglia; and even in these cases the gastroentero-anastomosis will be complementary to the pylorectomy. In case of progressive ulcer of the stomach, gastrojejunal anastomosis will be found useful, not to stop the hemorrhages, but to put the organ at rest and allow cicatrization of the lesion.

Murphy Button.—Dr. Murphy of Chicago had been announced to speak on ileus, but the complete discussion of intestinal anastomosis led him to give a few facts in relation to the button brought before the public by him eight years ago. He presented to the section a statistical list of 1620 cases in which the button was used. These cases including all kinds, malignant and non-malignant, acute and chronic, gave a mortality of 19.3 per cent.; 166 non-malignant cases showed a mortality of 2 per cent. He claimed that before the days of the button the lowest mortality was 30 to 40 per cent or higher, and that the first great drop in this mortality came with its introduction. He agreed that it was a little injudicious to leave a foreign body in the gastrointestinal tract over which the operator had no control, but he could not believe in absorbable buttons until they could be so managed that they would not be absorbed before Nature was ready to do without them. In some cases there is union at the end of three or four days, in others not for ten days or even longer. He was at present experimenting with a button made of magnesia and tempered with aluminum which he was not yet ready to put on the market. This button is not absorbable by the gastric juice, but may be made to dissolve by means of alkaline waters.

Forceps for Intestinal Anastomosis.—Dr. Laplace of Philadelphia demonstrated his forceps for employment in intestinal anastomosis. The method offers the following advantages: (1) Rapidity and accuracy of suturing without leaving any foreign substance within the gut; (2) an absolute control of the field of operation by means of the assistance of the handles of the forceps; (3) the facility with which the forceps are applied, preventing the escape of intestinal contents during the operation.

Dr. Doyen of Paris spoke of different methods of anastomosis and advocated as most scientific the Laplace forceps.

Isolation of the Appendix.—Dr. Ochsner of Chicago said that the vermiform appendix is located anatomically in a position in which it is easily isolated from the general peritoneal cavity. When inflamed the omentum at once surrounds the appendix and if left in a condition of rest, the elimination from the general peritoneal cavity is accomplished and the worst possible result is a comparatively harmless circumscribed abscess. The danger of disturbance of this condition comes from the peristaltic motion of the small intestines. This can be eliminated by giving the patient absolutely no food of any character and no cathartics by mouth until all acute symptoms have disappeared for at least four days, by removing whatever contents there may be in the stomach by gastric lavage and by employing exclusive rectal alimentation, making use of some concentrated predigested liquid food. This does not make operative treatment of appendicitis unnecessary but it changes a very unfavorable acute into a very favorable chronic condition. Extensive clinical observations support this form of treatment.

Transplantation of the Stomach.—Dr. Ullmann of Vienna detailed a number of cases in which he transplanted the stomach of young pigs into different parts of the intestine. The animals stood the operation well and though he stitched the stomach into the small intestine, the cecum and even the colon, digestion went on without apparent disturbance of function.

Pyloroplasty.—Dr. Segale of Genoa advocated in case of stenosis of the pylorus, when it is non-malignant, pyloroplasty by a new method. Instead of resecting the valvular portion of the stomach he makes a curved longitudinal incision from some distance, above the pylorus, through the pylorus and some distance below it. He now slides this incision up on itself and stitches it. This is so accomplished that the pyloric valve takes a spiral turn, so that an opening is left along the spiral.

Resection of the Rectum.—Dr. Jonnesco of Bucharest said that he had done resection of the rectum and pelvic colon by the abdominal-perineal method, accompanied by emptying of the pelvis for cancer of the rectum four times resecting 30 to 40 centimeters of the intestine, with two cures and two deaths. One of these died of peritonitis on the fifth day, the other of cardiac

collapse the day of the operation. Moreover, both cases were the extremes of what might be called operable cases, one on account of the great extent of the cancer, the other on account of profound cachexia. This operation is superior to all others because it assumes in operable cases the removing as far as possible of the chance of relapse and again it reduces the danger of the operation to a minimum. Admitting that removal wide of the tumor is the only rational radical treatment for cancer, it is necessary to resect the rectum entirely and have recourse to an artificial anus, and of all such it is incontestable that the iliac is the best.

Epididymo-testicular Tuberculosis.—Dr. Mauclaire of Paris said that since the publication of his first report last April he had done several new operations, and could give now the results of 18 cases. These results can be summed up as good, satisfactory, and bad. Good results, that is, atrophy of the whole infected mass, were obtained in all cases without suppuration or fistula. In the second category are those cases in which atrophy came about slowly; in one of these a fistula developed which was cured after four months. In the third class are those that were already suppurating and continued after the operation to infect the surrounding tissue, making necessary a second interference. From these results he believes the operation ought to take a place among those for epididymo-testicular tuberculosis. The operation is very simple, consisting simply of a double ligature of the cord and section between them.

Torsion of the Spermatic Cord.—Dr. Nanu of Bucharest reported one case that came under his notice in which the diagnosis was made certain by castration. Classical works make but little mention of this accident, and for this reason and the difficulty of making a diagnosis persuaded him to report the case. He believes that anatomical defect is necessary in its causation, probably most frequently on arrest in development of the testicle.

Nephrorraphy—Dr. Biondi of Sienna after insisting on the difficulties, etc., of other operations detailed his procedure. Having cut down on the kidney he puts it back in place and fixes it there by a pad of gauze placed in front of the organ. He then packs in gauze around the kidney in zigzags and allows it to remain for seven or eight days, when he removes the whole and permits the wound to heal. The cure is complete in about twenty days. He claims to have had 13 cures in 13 cases.

Tendon Transplantation for Paralysis.—Dr. Vulpius of Heidelberg drew the most favorable conclusions from 160 operations performed by him. He said that the most vigorous asepsis was to be carried out. He sacrifices no muscles, but places the peripheral end of the cut tendon in connection with the neighboring muscles. In this manner he benefits the paralyzed muscles without causing any loss to the healthy ones. The indications are: Traumatic loss of muscles, tendons and nerves; spinal paralysis, especially infantile spinal paralysis; and partial paralysis generally. He claims that transplantation shows total paralysis to be more rare than is thought. The most favorable place for the operation is the leg, the thigh coming second. The muscles of the forearm offer more difficulty, nevertheless he has had already very satisfying results even there. Relapses have become more and more rare as the operative technic was perfected, and in case of relapse he found that any mistake could easily be corrected by a second operation.

THE NEW YORK ACADEMY OF MEDICINE—SECTION ON SURGERY.

Stated Meeting, Held April 19, 1900.

The President, William H. Thomson, M.D., in the Chair.

Physiology of Internal Secretions.—Professor William H. Howell, of Johns Hopkins University, Baltimore, Md., said that three years ago he discussed this same subject before a congress of American physicians. Just then the subject of tissue-therapy and of internal secretions was attracting a great deal of attention, but the hopes that were raised by Brown-Séquard's experiments were not destined to be realized. There were insurmountable obstacles in the way of successful tissue-therapy. Some advances have been made in the last few years that seem worthy of notice. Originally, when it was noted that extirpation of the thyroid caused symptoms of myxedema or death, these results were attributed according to the theories of Claude Bernard and Brown-Séquard to the absence of the internal secretion of the gland. This theory seemed to furnish also the explanation for the benefit derived from the administration of thyroid in cases in which the gland was absent or defective. It seems to be definitely settled that there is an internal secretion of the thyroid gland and that its active principle is iodothyrin. There are two theories for the method of action of this internal secretion; the first supposes that certain toxins are produced in the course of normal metabolism, which act as poison within the body. These are neutralized by the secretions of the thyroid, which would thus form a kind of antitoxin. This theory involves the awkward assumption of a number of specific toxins and antitoxins for the purpose of carrying on normal metabolism. The other theory is that the thyroid secretion supplies an element which is necessary for healthy nutrition. Tissue-therapy with thyroid substance has been eminently successful.

Pancreas, Adrenals and Ovary.—Tissue-therapy with the pancreas and adrenals has been a failure. Curiously enough, however, ovarian extract has been productive of good in the hands of a number of conservative observers. It is well known what an influence the ovaries have

on general metabolism. As the result of oophorectomy women put on fat, the uterus and mammæ atrophy and certain nerve-symptoms of a very distinctive character occur. These observations on human beings are supported and confirmed by physiological experiments. It has been found that certain symptoms due to ovarian disease and certain affections due to impaired metabolism can be influenced for good by the administration of ovarian extract. Animals from which the ovaries are removed at first show no change in metabolism. At the end of six or seven weeks, however, there is a distinct decrease in the amount of oxygen used by the animal. On the other hand, when ovarian extract is given the amount of oxygen consumed by animals from whom the ovaries have been removed is increased. The oxygenation process in normal animals is not affected by the administration of ovarian extract. There are some differences of opinion as to these results, but the differences would seem to be due to the length of time that is allowed to elapse before observations were taken. It is only after six or eight weeks that this change in the consumption of oxygen is noticed. These observations with regard to the ovary are all the more interesting because it has been demonstrated that the ovary can be successfully grafted from one animal to another and even from one human being to another. The nature of this substance in the ovary which produces the action upon oxidation is not known. It has been suggested that it is probably of a ferment character and it has been spoken of as an oxydase or oxidizing ferment. Neither is it known from what tissue elements in the ovaries the substance is derived. It has been suggested that it originates in the corpus luteum. This is not improbable seeing the almost glandlike character of this structure.

It is an interesting observation that while castration in the male animal causes the same decrease in the oxidation process as does oophorectomy in the female, the administration of testicular extract to castrated animals does not increase the consumption of oxygen in the male, while the administration of ovarian extract causes the increase in the male as well as in the female.

Parathyroids.—Some years ago the question of the removal of the thyroid and its effects seemed simple and settled. Of late years, however, it has come to be recognized that the parathyroids, small glandular bodies lying in the neighborhood of the thyroid, play an important rôle in the effects produced by thyroidectomy. It was formerly throught that these little bodies consisted of embryonic thyroid tissue which occasionally developed into fully-formed thyroid tissue after the removal of the thyroid. This hypothesis was not supported by observations. It is now known that the little bodies have a function of their own and that they are probably more important to the economy than even the thyroid itself. When the parathyroids are removed the muscular trembling, the apathy, the malnutrition and the acute marasmic condition which it was customary to attribute to acute thryroidism develop. Moussu attributes the chronic constitutional weakness which leads to death to removal of the thyroids. Rapid death, however, is due to the parathyroids and each of these sets of glands has a secretion peculiar to itself. The parathyroids contain iodine in notable quantities. This is as much as we know yet of their secretion. Clinically we have not so far been able to employ parathyroids for any purpose.

Adrenal Therapy.—That there is an internal secretion from the adrenals there seems to be no doubt. Long ago it was noted that adrenal substance caused a rise of blood-pressure. Then it was noted that there was in the blood of the adrenal veins a substance which caused such a rise of blood-pressure if injected into the same or another animal. The amount of this substance contained in the adrenal veins could be increased by irritation of the splanchnic nerves. In a word, the adrenals act as true glands with the reflex nerve-mechanism possessed by ordinary glands that have a duct. If a cannula be put into the adrenal vein and the blood collected and the peripheral end of the cut splanchnic nerve be stimulated electrically, the blood obtained is not more in quantity in a definite time than before, but it contains more of a substance that causes a rise of blood-pressure; that is, there is not a more rapid flow of blood from the gland, but there is greater secretory activity. Ewald thinks that he has obtained the active principle of the adrenals. It is epinephrin, a rather simple body. It has a curious chromogenic effect which connects it with Addison's disease. The effect of the substance is, however, only passing. Hence it is that the use of adrenal has not been successful in Addison's disease. The constant presence of a certain amount of adrenal substance is required to prevent the symptoms of that disease, and, as it is very easily broken up in the circulation, success would require constant injection. The only way to make up for diseased adrenals is by grafting methods. There is some promise in this form of treatment, but it has not yet been successfully accomplished. The action of adrenal substance is peripheral not central. After the spinal cord has been destroyed adrenal extract still causes constriction of the blood-vessels. In the dog the destruction of the spinal cord may cause a fall of blood-pressure from 150 millimeters to 20 millimeters. Restoration of the blood-pressure will take place almost immediately after the administration of adrenal extract. The effect is, however, only temporary and the remedy would have to be administered almost constantly to be of lasting effect. For this reason adrenal substance is not likely to be of any value in surgical shock.

Internal Pancreatic Secretion.—The evidence as to the existence of an internal secretion of the pancreas is practically complete. Extirpation of the pancreas is followed by a glycosuria which

becomes a true diabetes even when starch is not consumed; 8 to 10 per cent. of sugar appears in the urine and the ordinary symptoms of diabetes develop, thirst and hunger and emaciation, while oxybutyric acid appears in the blood. On the other hand, when the duct of the pancreas is closed by an injection of paraffin, while the nutrition of the animal suffers the glycosuria that results is only a passing incident. If only a small amount of pancreatic tissue is left, about one-fifth, true diabetes does not develop. Transplantation of the pancreas suffices to prevent the diabetes. Human and pancreatic diabetes seem to be the same affection. It is true that often in the human being no change has been found in the pancreas, but it must be remembered that our methods for the investigation of such changes are crude. It is very probable that changes in the cells of the pancreas make the difference in function which gives rise to diabetes. It is very interesting to note that, while in true diabetes the power to use dextrose is lost, the power to use levulose often remains. It is probable, therefore, that the internal pancreatic secretion is an enzyme, which somehow brings about the conversion of dextrose into other forms in which it is available for purposes of metabolism. Whatever this enzyme is it must be peculiarly constituted so as to fit into one form, *viz.*, the dextro-rotary of sugar, as a key into a lock, while another corresponding substance fits into the levo-rotary form of sugar. Lepine has found a glycolytic enzyme in the blood which acts upon sugar. He assumes that this is the internal secretion of the pancreas. The blood of the depancreatized animals has much less glycolytic power than that of normal animals. There is more of the glycolytic faculty in blood from the pancreatic vein than from elsewhere in the body. Other observers have denied this glycolytic enzyme to be pancreatic and have said that whatever fermentative action there is occurs only in shed blood and is the result of the disintegration of leucocytes. The use of pancreatic extract has been absolutely unavailing in true diabetes. There is some hope that transplantation of the pancreas may yet accomplish something in the therapeutics of the disease. Pancreatic grafts cure diabetes in animals that has been caused by the removal of the pancreas. The transplantation is difficult to perform, however, and so far has not even been tried on the human being.

Essential Internal Secretions.—The internal secretion of at least three and probably four glands is absolutely necessary to life. They are the thyroid, the adrenals, the pancreas and probably the parathyroids. There are others of whose function we are not yet sufficiently assured. Only during this last decade have we come to realize the importance of the pituitary body, for instance, in important nutritional processes. Time was when nutrition seemed simple chemism between the cell and the food-stuffs presented for its use. Now we know that there is a complicated system of check and countercheck on all cellular processes. Trophic nerves have their influence on all functions and every tissue of the body must be keyed up to its proper tone by specific secretion. Where simplicity seemed to reign the course of investigation has brought us face to face with greater complexity. Progress, however, is constantly taking place and each new advance is a source of encouragement.

In the discussion Dr. Blake said that the active principle of the suprarenals seems to affect especially the muscular walls of the blood-vessels. From it there results a latent dynamic impulse. This seems the best explanation of its effect. While on the healthy heart adrenal substance has no effect, on diseased hearts it has a very marked action. When absorbed from the stomach its power seems to be neutralized by the digestive ferments. Absorbed from mucous surfaces, however, it acts to prevent cardiac intermittence and in mitral insufficiency it is the best cardiac regulator we have. Mitral murmurs have been known to disappear during its use. On aortic insufficiency it has no effect.

Importance of Parathyroids.—Dr. Cunningham said that he has been very much interested in the problem of the significance of the parathyroids. In the dog there are two of these organs on each side, one lying within and the other without the substances of the thyroid gland. The latter is rather easily removed; the other not without great injury to the thyroid. Instead of removing the thyroid Dr. Cunningham has experimented in another way. After loosening all the connections of the thyroid but leaving its blood-vessels intact, he surrounded that structure by a purse of animal membrane and then inserted drainage at the lower end of the wound. All three of the dogs on which he experimented developed mild tetany, restlessness, a state of malnutrition and myxedema. One of them was killed at the end of a month, the other two died at the end of two months from a subacute cachexia. This experiment would seem to prove that there is some substance given off by the thyroid that produces a distinct effect on metabolism and preserves the organism from an autointoxication. In these experiments the parathyroids were not disturbed, so that the question of their significance to the organism seems to be an open one.

Addison's Disease and Adrenal Therapy.—Dr. William H. Thomson said that, despite the fact that reports of the use of adrenal substance in Addison's disease had usually been unfavorable, he had two cases to report in which the benefit derived from this method of treatment had been most striking. All the other cases of Addison's disease except these two that have come under his observation have proved fatal in twenty months or less. The first successful case was a farmer who came under treatment four years ago. There was absolutely no doubt of the diagnosis of the disease, yet under the influence of adrenal extracts his symptoms abated and he has

continued to enjoy reasonably good health up to the present time. The second case is that of a theatrical manager who came under observation three years ago. He has been seen by some of the best consultants in the city and all are agreed that he is suffering from Addison's disease. In his case the symptoms have abated; especially the intense tiredness and disinclination to exertion have lessened and he has been able to continue his occupation. He is at present abroad attending to his business.

In closing the discussion Dr. Howells said that the physiologists have no theory as to the action of the adrenals, except that some substances which they secrete have an effect on blood-pressure. In the same way they have an effect on the heart, but this is very passing. As to the difference of their action on normal pathological hearts there are as yet not enough observations recorded to justify the construction of a theory in explanation of the action. Further observations are required in order to make clear just how thyroid acts on the heart in pathological conditions.

The important thing in adrenal ductless-gland therapy, as we see it now, is the possibility of grafting portions of glands in cases where degeneration of the original gland has taken place. Experiments in this line are well worth the trying. It is an extremely difficult procedure, but improvements in technic will undoubtedly make it possible and open up a very glorious prospect for tissue-therapy.

As to the parathyroids, it is to be remembered that their importance has been claimed as the result of the experiments of Professor Gley, who is one of the best-known physiological experimenters in the world. His observations have been confirmed by other conservative physiologists and in general considerable weight is placed on the conclusions which he announced.

REVIEWS.

The Soul of Man. An Investigation of the Facts of Physiological and Experimental Psychology. By Dr. Paul Carus. The Open Court Publishing Co., Chicago.

There are certain features in this production that approach the unique. In the prefatory chapter man's soul is stated to be something mysterious, wonderful and marvelous, and it is certain that the author has in its exposition made it fully up to contract. We do not know where we have ever found such a disjointed exposition of the subject, but perhaps it is a cavil to imagine that the soul of man is aught but a "thing of shreds and tatters."

The work consists of a series of short essays on various interesting topics, interspersed with badly-reproduced pictures of the nervous system of different animals. The essays rarely rise above the level of mediocrity and as for the relationship of the several parts it is almost impossible to comprehend their coherence. The facts in the main were true for the time when they were written, mostly twenty years ago. Some of the deductions, however, are worthy of serious consideration both for their muddy logic and inaccuracy. We commend one of these to the pregnant woman. "Child-bearing in itself, the growth of a new being, is neither pleasurable nor painful. It often becomes painful by the many disturbances which it is but too liable to cause." We can hardly realize that Dr. Carus has had much personal experience in the matter. The work is amusing, however, and for those but partly trained in physiology or psychology will prove of interest and, if further supplemented by later classics, will be profitable.

BOOKS RECEIVED.

Text-Book of Practical Medicine. By William Gilman Thompson, M.D. Illustrated by 79 Engravings. Lea Brothers & Co., Philadelphia and New York.

Dictionary of Medicine. By Alexander Duane, M.D. Third Edition, Enlarged and Thoroughly Revised. With 8 full-page Colored Plates. Lea Brothers & Co., Philadelphia and New York.

Manual of Surgical Treatment. By W. Watson Cheyne, M.B., F.C.S., F.R.S., and F. F. Burghard, M.D. and M.S. (Lond.), F.R.C.S. In Seven Volumes. Vol. III. Surgical Affections of the Bones and Amputations. Lea Brothers & Co., Philadelphia and New York.

Transactions of the American Microscopical Society. Twenty-Second Annual Meeting, 1899. Vol. XXI. Edited by the Secretary.

Manual of Personal Hygiene. Edited by Walter L. Pyle, A.M., M.D. Illustrated. W. B. Saunders & Company, Philadelphia. $1.50.

Atlas and Epitome of Diseases Caused by Accidents. By Dr. Ed. Golebiewski of Berlin. Translated by Pearce Bailey, M.D. Illustrated. W. B. Saunders & Company, Philadelphia. $4.00.

Atlas and Epitome of Gynecology. By Dr. Oskar Schaeffer. Edited by Richard C. Norris, A.M., M.D. Illustrated. W. B. Saunders & Company, Philadelphia.

Clinical Examination of the Urine and Urinary Diagnosis. By J. Bergen Ogden, M.D. Illustrated. W. B. Saunders & Company, Philadelphia. $3.00.

Retrospect of Medicine. Edited by James Braithwaite, M.D., Lond., and E. F. Trevelyan, M.D., Lond., B.Sc., M.R.C.P. Vol. 121. January-June, 1900. Simpkin, Marshall, Hamilton, Kent & Co., Limited, London.

The Law in its Relations to Physicians. By Arthur N. Taylor, LL.B. D. Appleton & Company, New York.

International Clinics. Edited by Henry W. Cattell, A.M., M.D. Vol. II. Tenth Series. J. B. Lippincott Company, Philadelphia.

A Hand Book for Nurses. By Dr. J. K. Watson. American Edition under Supervision of Dr. A. A. Stevens. Demi 8vo., 413 pages. Illustrated. W. B. Saunders, Philadelphia.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVII. NEW YORK, SATURDAY, SEPTEMBER 8, 1900. NO. 10.

TROPHIC CHANGES IN CONSUMPTION: A CONTRIBUTION TO THE SYMPTOMATOLOGY OF THIS DISEASE.[1]

BY HENRY HERBERT, M.D.,

OF NEW YORK;

PHYSICIAN TO THE MONTEFIORE HOME COUNTRY SANITARIUM.

TUBERCULOSIS is a disease, the beginning of which cannot always be traced. The early symptoms do not always mark the beginning of the tuberculous era, as has already been pointed out by Maraglinio. Although it is claimed that it takes from one to three years from the beginning of the infection to the full development, it may safely be said that the shadow of phthisis is cast long before its actual appearance; we can trace it back years and decades to the scrofulous era, and some authors go still further, declaring that consumption is directly inherited. Baumgarten[12] is the foremost supporter of this theory, which is decidedly opposed by Virchow, Cohnheim, Cornet and others. A more acceptable enunciation of Baumgarten is that scrofulosis is already tuberculosis, because it is proven that the products of scrofulosis generate tuberculosis. He regards scrofulosis as a kind of tuberculous sequel and the latter as a recrudescence of the early developed disease. I consider scrofulosis as having a certain analogy to syphilis in that it constitutes the primary and secondary stages of tuberculosis and like syphilis, being curable in these stages, reappears as tuberculosis of the lungs or of other organs like the tertiary lesions of syphilis. During this "latest" stage—an expression introduced by Cohnheim—there is developing a scrofulo-tuberculous stigma, which finds its prototype in the phthisical habitus of individuals with the so-called hereditary taint. I say "so-called" because I am not a believer in the hereditary theory of consumption; I agree fully with the most radical views regarding the infectiousness of that disease; the so-called "disposition" I consider an already existing manifestation of phthisis, believing further that undue exposure is the only source of consumption. That the offspring of consumptives often become tuberculous is not a proof to the contrary, it simply shows that the disease is easily transmitted by intimate domestic and social relations. On the other hand it has been proven[7] that children taken away in due time from the infectious focus usually develop into normal and healthy individuals, unless they are subjected to new infection. It is furthermore not uncommon to see the healthiest and wealthiest individuals afflicted with this dreadful disease, individuals whose family history is perfect.

[1] Read before the German Medical Society, February 5, 1900.

The area involved by the symptomatology of consumption is very extensive, nearly every organ may be affected, either directly by germs or indirectly in the form of so-called trophic changes, which may be caused by a virus, soluble protein substances circulating in the blood. The pathologic importance of some of these trophic changes is increased by the fact that they appear on the same side of the body as the diseased lung. This unilateral appearance of symptoms was first mentioned by Schaffer in 1878, but only in regard to diseases of the upper air passage; later Solly made mention of this peculiarity in regard to the nasal affection. I have found similar unilateral symptoms in other organs, which have not yet been described in the literature of the subject; my observations were made mostly on male consumptives of the Montefiore Home and of the Country Sanitarium at Bedford Station, N. Y.

The pathologic basis for the term "habitus phthisicus" is formed by changes in the skeleton, the etiology of which can be traced back to the scrofulous era. Strophies of single bones have been described, but they do not show any signs of phthisis particularly, except that they are apt to occur primarily in the ribs. The following are significant factors[6]: rapid growth of bones, ossification of the costal cartilage, disproportion between the width and depth of the thorax to its length, prominent angulus Ludovici, narrow scrobiculus cordis. Among the unilateral symptoms may be included scoliosis, depression of one shoulder, a wing-like protrusion of one scapula; the latter caused by atrophy of the musculus serratus magnus. Regarding the disproportions and deformities of the chest, I wish to state that they do not occur in adults with a normally developed skeleton, except scoliosis, and if we do observe it in such individuals we may safely assume that they had acquired such "thorax paralyticus" through tuberculosis in infancy or earlier childhood. Good muscular stratum and a strong panniculus adiposus may easily cover those abnormalities.

E. Fränkel[2] and others have described atrophy and degenerative changes in the muscles of consumptives, consisting of a decrease in the number of the primitive bundles, a granular degeneration and fine granular pigmentation of the same. The emaciation starts mostly in the neighborhood of the thorax and especially in the inspiratory muscles. Visible unilateral atrophy may implicate the intercostal muscles causing thus, with the atrophic ribs, flattened or deepened intercostal spaces; similar changes in the pectoralis major, supraspinatus and serratus magnus cause flatness in the re-

gion of their location. Considerable importance was formerly ascribed to the so-called "idiomuscular contractions," but according to Cornet this was contradicted by Lawson Tait, Stadelman and v. Ziemssen. T. W. Moore[19] states that "myotatic irritability of the pectoral muscles and of the platysma myoides is a valuable sign." Although I acknowledge the value of this sign in the pectoral muscles, I do not agree with the latter writer regarding its value in the platysma, because I found exactly a contrary reaction in this muscle on the affected side. If we tap with the percussion-hammer or any similar instrument the insertion of the platysma along the clavicula we will notice in healthy individuals lightning-like fibrillary contractions of the muscle. This reaction I found diminished 37 times out of 65 cases of phthisis on the same side as the lung was found diseased.

The emaciation in phthisis is due mainly to the disappearance of the fat and the atrophy of muscles. Strauss and Gamaleia noticed a rapid destruction of the panniculus adiposus after injections of dead germs and they attributed this result to the action of proteid of the dead germcells: Mafucci, Prudden and Hodenpyl have produced marasmus by the same means. But how can we explain the unilateral muscular atrophy of the thorax in phthisis? As it is well known, we observe on the affected side an insufficient expansion, a retardation during respiration, and the question is raised, are the muscles atrophic on account of their inactivity, or does the lung remain inactive on account of the atrophy of the muscles? The lung follows passively the respiratory excursions of the chestwall, and it seems therefore that the activity of the muscles is diminished on account of a reflex impulse from the diseased lung, and here we observe therefore besides the atrophy due to general causes also a local atrophy due to inactivity. By means of systematic exercises I was enabled to increase the expansion of the thorax and of the lungs in consumptives, utilizing thus the idea that strengthening of the respiratory muscles causes also a strengthening of the lungs.

The blood[8] also takes part in the general atrophy and shows changes similar to those observed in cachexia and marasmus. According to Rokitansky,[6] Brehmer and Andral the heart of consumptives is smaller than normal, and Beneke asserts that a congenitally small heart increases the disposition to consumption. Dr. W. Hutchinson,[22] who made 215 autopsies on different animals, says that there exists a certain relationship between the size of the heart and immunity against tuberculosis in animals. I am of the opinion that the smallness of the heart is rather the result of consumption in the early age, whereby the vagus becomes affected and influences the growth of the heart by means of the trophic fibers known to exist in this nerve. Histologically partial and complete atrophies have been described by Leyden, Venn, Strümpell and others; atrophy of the vagus by Vierordt,[7] of the phrenicus by Heine.[7] Jouanneau[7] describes a case of tachycardia in consequence of compression of the left vagus and phrenicus caused by pleuro-pericarditic adhesions (Cornet).

Tachycardia is furthermore caused, according to Riegel, Becker and others, by tuberculosis of the bronchial glands; according to Marfan[21] it is caused by diminution of the respiratory surface. Neither theory seems to be plausible, because irritation of the vagus causes retardation of heart action and on the other hand we notice tachycardia also in cases where there is only a very small respiratory area affected. It is possible that there is an irritation of the accelerator cordis nerves caused by proteids, circulating in the blood, or that certain fibers of the vagus, the so-called inhibitory fibers, are atrophic and thus the functional activity of the antagonistic nerves, the accelerantes, preponderates.

Complications of the upper air-passages in phthisis have a certain etiologic and symptomatologic significance. From the history of the patient the fact is often elicited that these parts were involved prior to the appearance of the pulmonary symptoms and often on the same side. Schäffer[1] in his statistical researches on the relationship of laryngeal disease to lung troubles has proven that long before the clinical diagnosis is established there are pathologic changes in the pharynx in the cavum pharyngonasale, hypertrophy of the tonsils, otitis media, and paresis of the soft palate on the same side on which the lung affection appears at a later period. Schäffer has observed this correspondence in 302 cases, or in 50.3 per cent. Solly[20] found this coincidence between the side of the nose and the side of the chest affected in 65 per cent. of his cases. Krieg, according to Cornet, observed the remarkable fact that out of 275 cases of unilateral tuberculosis of the larynx 252 cases or 91.6 per cent. had tuberculosis of the lung on the same side. In 21 cases of ear complications I found 20 on the same side as the affected lung. According to Schäffer, Cornet and others, paralytic vocal cords and hoarseness are the first manifestations of an impending or already existing lung affection; according to Luschka the recurrent nerve is the cause of this paralysis or paresis.

Mouth-breathing is also a characteristic feature in consumption, caused by chronic catarrh of the mucous membranes of the nose or by adenoid growths, and it is claimed that it is quite often the cause of primary infection of the lung.

The Fredericque-Thompson[3] gum symptom was formerly considered a valuable sign in incipient consumption, but this was disproved by G. Sticker, who examined 1000 cases for this symptom. Caries of the teeth appears more often in the early than in the later stages of the disease; the same may be said of the fetid breath. Conjunctivitis, blepharitis, chalazion[15] are rather early symptoms of phthisis and may be looked upon as evidences of the scrofulous diathesis.

More interesting are the paretic symptoms of the eye. In his text-book E. Fuchs mentions tuber-

culosis as a cause of paralysis of the eye muscles. I have observed impairment of sight in the beginning of consumption, but am not in the position to give further statistical data. Inequality of the pupils, which usually manifests itself as the paralytic form of mydriasis is a valuable sign in phthisis and gains in importance because of its nearly constant equilateral appearance, an occurrence which to my knowledge has not yet been described. Destre found inequality of the pupils in 97 per cent. of his cases; I have seen it in 75 out of 78 cases; of these 75 cases 66 showed the sign on the same side as the lung affection. The dilatation of the pupil is dependent upon the sympathetic, which gets its fibers, destined for the pupil, from the ciliospinal center; hypertrophied glands, it is claimed, produce an irritation of that center. I found that pilocarpine instillations caused disappearance of that symptom. Lately I have observed a greater pigmentation of the iris and of the mammilla on the same side as the diseased lung. Both symptoms belong to the early stage of consumption and have thus far not been mentioned in the literature of the subject, and I believe that the latter, the mammillary symptom, has some diagnostic value. Out of 82 cases I noticed the variation in pigmentation of mammilla in 74 times or in 92 per cent.; in 27 one-sided lung affections there was more pigmentation 25 times on the affected side; in cases where both lungs were affected the symptom prevailed on the more affected side.

The skin undoubtedly offers a great field for the discovery of trophic changes. According to Cornet, "the skin in phthisis becomes rough, dry, scaly; its color becomes sallow, gray, pale and is often changeable." Hyperhydrosis sets in early. Cornet observed it exceptionally on one side; I have frequently observed sweat-drops in phthisical patients during examination in the axilla and on the inner surface of the upper arm also in individuals who did not suffer from hyperhydrosis.

Hypersecretion[7] of the sebaceous glands is also common and gives the skin a fatty appearance and seems to be the cause of comedones in the early stages of consumption. Herpes zoster, a rare occurrence, stands according to Rendu[11] in causal connection with tuberculosis. Acne appears in the early stages of consumption; in 89 patients I have observed it 58 times and among these there was a more extensive eruption noticeable on the affected side in 26 instances. Pityriasis versicolor was wrongly associated with tuberculosis, although it is a fact that it appears quite frequently during the later stages of this disease; Barduzzi[5] made inoculations with the pityriasis detritus and caused tuberculous nodules. These results were affirmed by Dagnet and Haricourt, but Cornet insists that the experiments were wrongly conducted.

Pityriasis tabescentium[7] is a late sign, also chloasma phthisicorum, a hyperpigmentation of the skin in the later stages of phthisis. Both symptoms are rare and are not characteristic of the disease.

Little attention has been paid in the literature of this subject to loss of hair. Defluvium capilitii is a well-known, although not characteristic occurrence in chronic tuberculosis. I also have found quite regularly a partially diminished growth of hair on the thorax of the affected side, and in one instance I noticed the hair on the affected side turning gray. Among 118 consumptives I have found this "atrophy of the hair"—as I would like to call this symptom—100 times; in 14 of the 18 negative cases there was no growth of hair on either side, thus leaving 4 negative cases in a total number of 104. Among 100 cases of atrophy of the hair 95 corresponded to the affected lung, or 95 per cent. I wish to add that these 100 cases included all types of consumption, acute and chronic, unilateral and bilateral. Thirty-four cases of unilateral pulmonary affection were observed, and in these the symptom mostly appeared on the affected side; in cases of bilateral pulmonary disease atrophy of the hair was noticed on the side first involved. In 4 cases of arrested unilateral affection, hair atrophy was noticed on the formerly diseased side. These hair defects appear mostly on the anterior surface of the thorax, around the mammillæ, on the upper part of the thorax, on the shoulders and on the back. This symptom varies not only in extent, but also in intensity; in old chronic cases it is more striking. Microscopically there are no differences to be found.

As a consequence of these nerve-atrophies previously mentioned we may find disturbances of sensibility, of the vasomotor system, and even edema of the skin (Strümpell). In some cases I noticed a diminished reaction to mechanical irritation of the skin. Cyanosis of the skin with club-shaped fingers[10] is a valuable although not a pathognomonic sign in tuberculosis of the lungs. This deformity of the fingers depends, according to Litten, on hypertrophy of the soft tissue and not of the bones. Independently of the latter symptom there is noticed a striking, rapid growth of the nails, which gives them a claw-like appearance (Dufour).[10]

Glands are affected only through infection, and this mostly indirectly. Schlenker[1] described some cases in which the side upon which there were hypertrophic glands and tonsils corresponded with the side of the lung affection, but he did not make this differentiation in his article on that subject. It is known furthermore that the mamma also becomes involved in the general atrophy and lately I have observed in two phthisical girls a decided atrophy of the mammæ on the affected side. In women such a difference is not uncommon, but when observed in girls it may be of diagnostic value. A girl of twenty, whom I examined lately, claimed that four years previously she had some lung trouble with spitting of blood; she was sent to the mountains and recovered after one year. Since then she has suffered from shortness of breath and occasional slight pain in the left side. Examination of this somewhat anemic but strongly-built girl revealed

a diminished respiratory murmur of the left lung, left pupil enlarged, left mammilla more pigmented and decidedly smaller.

The liver presents a much more striking picture of the tuberculous diathesis. According to Ziegler, fatty degeneration regularly occurs in acute phthisis; Pitt[17] says that 22.5 per cent. of cirrhosis patients die of phthisis. Osler says:[17] "A remarkable feature in cirrhosis of the liver is its association with acute tuberculosis." C. R. Burr claims that the liver is more often affected in phthisis of the left lung. Burr, as is Aufrecht, is an advocate of the paretic theory of the origin of tuberculosis and attributes to the vagus, phrenicus and their connections the etiology of the tuberculous diathesis and as a further consequence of this disease mentions diabetes mellitus, one of the most dreaded complications in phthisis. It is claimed that an impaired function of the liver cells is the cause of this complication. The modifications occurring in phthisis in consequence of diabetes are, according to Blumenfeld,[18] absence of hyperhydrosis and decrease of fever. Hemorrhages are also seldom in that stage (v. Leyden, v. Noorden). Bartholow[17] found an abnormal secretion of urea in the urine of consumptives.

To complete the description of these indirect symptoms I have to mention among the earlier ones, gastric disturbances; among the later ones, impairment of the intellect and increase of the sexual desire; and among the terminal ones, amyloid degenerations. With the enumeration of all these signs I have by no means exhausted the subject, and the question arises, what is the cause of these unilateral disturbances?

Is it the virus which is circulating in the blood? Surely not. Are these signs produced by continuity from the diseased foci? This supposition does not seem any more plausible. It seems to be a degeneration of the trophic fibers in the nerves of the parts affected and we may ask, are these nerve-atrophies of primary or of secondary origin? Aufrecht, Burr and other adherents of the so-called paretic etiology of consumption, believe the trophic changes in the tissues to be the primary ones; that the bacillus finds a suitable nidus in that impaired tissue and then causes the well-known symptoms by its subsequent growth and development. Although we cannot deny that this hypothesis deserves some consideration, its truth has not been proven by positive demonstration. It is more likely that the bacillus is the primary cause; that the nerve termini become affected in the diseased tissue, as they do in septic infection, developing ultimately into a chronic degenerative atrophy of the nerves. The frequent occurrence of neuritis, as shown by histological researches, fully justifies this supposition.

In conclusion I wish to illustrate by a few cases the curious coincidence of the side on which the trophic signs occur and that in which the lung is diseased.

Case I.—Acute phthisis with cavity of right lung. B., nineteen years of age, sick about one year; family history negative. Inspection reveals: Right shoulder lower, right scapula deviated, right pupil enlarged. Atrophy of hair on right side of thorax, right mammilla more deeply pigmented, platysma reaction on right side very much diminished. In addition there have been acne defluvium capillitii and caries of teeth from the beginning of the disease.

Case II.—Chronic tuberculosis of the right lung with recent infiltration of the left lung. S. S., twenty-seven years of age, sick seven years; family history negative. For seven years he has been hoarse, right side of nose was operated on three times, right tonsil larger; atrophy of hair, pigmentation of mammilla and iris, paresis of platysma on right side. Acne frequent on left side, caries of teeth from the beginning.

Case III.—Cured tuberculosis of right lung. Dr. B., physician, was attacked nine years ago with consumption; after three years supposed to have recovered. During the acute stage he suffered from disturbances of eye sight of the right eye, right otitis, nose and thorax affection, pain in right side and right testicle. Formerly he had good teeth; during his sickness he lost six of them but none since his recovery. He gained eighty to ninety pounds, was married, had healthy children and attends to his professional duties without interruption. Examination reveals: Right pupil enlarged, hair atrophy and paresis of platysma on right side.

Case IV.—Latent tuberculosis. H., twenty-eight years of age, engineer; consumption in family; had pneumonia (?) three times, mumps at twenty-six, measles at twenty-seven; from fourteen to sixteen there was spitting of blood; he has always coughed and was subject to colds. The examination of lungs reveals on right side nothing positive; on left side, in posterior axillary line, there are fine crepitant râles. Inspection: Right shoulder lower, right scoliosis; dilatation of pupil, hypertrophy of tonsil, hair atrophy on right side. Acne and pityriasis on left side. Quick growth of nails, which are curved, caries of teeth and defluvium capillitii.

The objective evidence of the last case justifies the diagnosis of an obsolete affection of the right lung with a slight acute exacerbation of the left lung. The discovery of early or latent tuberculosis, as is known, often causes great difficulties and the tuberculin test does not always give satisfactory results; besides its application has some difficulties for the practising physician because of the refusal of the patients to submit to the test.

I am confident that the present results, although obtained from a proportionately small number of cases will be verified by the investigation of more extensive material. The practical results of these researches, briefly enumerated, are the possibility of recognizing the early and latent stage of consumption sooner than with the present means or methods; in acute cases, to as-

certain the side affected, if the physical examination does not give satisfactory evidence. If both sides are affected, these signs make it possible furthermore to ascertain the side primarily affected, on account of the occurrence of trophic disturbances on that side, and in cured cases to diagnosticate the location of an obsolete phthisis.

THE EFFECT OF FLASHES OF ELECTRIC LIGHT ON THE EYE.[1]

By DUNBAR ROY, A.B., M.D.,
OF ATLANTA, GA.;
CLINICAL PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS OF ATLANTA; OCULIST AND AURIST TO GRADY HOSPITAL, ETC.

Although some of the cases here reported occurred in my practice more than four years ago, they were recently recalled to my mind by reading Professor Haab's article (*Klin. Monatsbt. für Augenheilkunde*, July, 1899) entitled "Traumatic Macular Changes Produced by Electric Currents." There have been perhaps more cases observed than reported of temporary injury to the eye through intense electric flashes, but the rarity of such cases warrants the present presentation which will at all events call attention to the lurking dangers of the electric light.

Case I.—Mr. E., aged twenty-nine years, one of the chief superintendents of the city electric-light company, consulted me in my office May 20, 1895. The history given was as follows: About one hour previous, while he was trying to adjust some wires, two of them became crossed a short distance in front of his eyes and a blinding flash of light resulted. For a few minutes his vision disappeared, but gradually returned, leaving only a marked burning irritation in his eyes, the reason for the present consultation. On examining both eyes, a marked pink zone of injected blood-vessels could be seen around the cornea. Vision in both eyes was normal. He complained only of a smarting sensation about the lids and a slight amount of photophobia. The use of dark glasses, hot fomentations to the eyes and absolute rest for a few days was the only treatment advised. About two o'clock that night I received a telephone message saying that Mr. E. was suffering so much pain in his eyes that he desired me to come immediately to his house. On arriving I found both eyes a little more congested than on the previous examination. He was suffering from violent aching pains in the eyeball. On close examination the cornea was found to look a little hazy, a condition which was not present when he was at the office. There was marked photophobia. Several drops of a two-per-cent. solution of cocaine were instilled into the eyes and also a drop of weak atropine solution. In about fifteen minutes the patient was perfectly easy and reported next morning at the office that he had remained so all night, and even then he was perfectly comfortable. On examination the cornea was found to be clear and all signs of irritation had subsided. His eyes rapidly returned to the normal state. No changes could be seen with the ophthalmoscope, although the symptoms pointed to a decided retinal irritation.

Case II.—Mr. M., aged eighteen years, also an employee of the Georgia Electric-Light Company. The history of this young man was almost identical with that of Case I., with the exception that he was not seen until two days after the injury. A similar electric flash took place just in front of his eyes and he was also blinded for a few minutes. On recovering from the shock he bathed his eyes in cold water, and except for a slight irritation he experienced no discomfort. The irritation persisting the company sent him to me for examination. R.E., V., 20/30. Improved by no glass. L.E., V., 20/30. Decided ciliary injection in the right eye and very slight in the left. Pupils react to light and accommodation, but appear rather contracted. The cornea of the right eye appeared a little hazy. By ophthalmoscopic examination I must acknowledge that nothing abnormal could be discovered, although the region of macula in the right eye may have looked a little cloudy. Neither in this case nor in the first was any scotoma or contraction of the visual field to be found. The patient was ordered to wear dark glasses, use hot fomentations to the eyes, and a drop of atropine solution was instilled into both. He had no further trouble and vision in both eyes became normal. The flash of light in both cases came from wires carrying a 500 voltage.

Case III.—E. L., aged fifty-two years. Admitted to Grady Hospital on account of an accident similar to Case II. This case was almost identical with the one just reported both in symptoms and the treatment employed.

A few cases have been reported in which intense electric flashes have caused a temporary blindness in which the pathologic lesion has been a grayish discoloration in the region of the

[1] Read before American Ophthalmological Society, Washington D. C., May 1–3, 1900.

macula lutea. The action of snow upon the eyes, producing the phenomenon known as "snow blindness," is of no infrequent occurrence in the frigid zones, and the pathologic conditions there found are quite similar to those seen in the eyes which have been injured by electric flashes.

The subject of pathologic changes in the macula lutea due to traumatic causes first obtained prominence in an article by Professor Haab of Zurich at the Seventh International Ophthalmological Congress held at Heidelberg. Since that time Professor Haab and his associates have continued to study the subject and given at intervals further contributions relating to these traumatic changes. In 1889 E. Meyer of Zurich delivered an inaugural address upon this subject, and in 1896 A. Siegfried of the same city and of the same clinic published an extensive article upon "The Traumatic Changes in the Macula Lutea of the Retina."

Intense light as the cause of retinal and conjunctival changes has been known to careful observers for a long time. Electric light as a cause is of comparatively recent date, and only since it has become so universally popular for domestic use. One has but to note the dazzling effect produced upon the eyes by the bright reflection of the snow or the same effect when we gaze, unaided by tinted glasses, upon the sun in partial eclipse, to realize how irritating and blinding such lights are to our visual members. "Snow-blindness" has been known to ophthalmologists for years, as has also the blinding effect of bright sunlight upon the eyes.

A very interesting discussion of this latter subject with an abstract of all cases can be found in an article by Mackeye, published in the *Ophthalmic Review*. He found that after exposure of the eyes to sunlight the patient noticed a dark spot in the field of vision. This on examination was found to be a positive scotoma which lasted for a certain period of time and then passed away. Mackeye also found that this represented color-scotomata extending over a large area. Patients in such a state will often see objects twisted, producing the condition known as metamorphopsia. The ophthalmoscope will sometimes show no changes, whereas in others a decided hazy condition will be found in and around the macula, occasionally with an accompanying pigmentation. Vision as a rule is reduced, and when this is marked recovery rarely takes place. Pigmentation of the retina caused by the action of sunlight has been adduced by Monoyer as a cause of the condition known as "retinitis pigmentosa." Deutschmann has shown by experiment that concentration of the direct rays of sunlight upon the retina of a rabbit produces a coagulation of the retinal albumen with an accompanying pigmentation. However, such an analogous condition could not be attributed to the action of the sunlight upon the eye. While the action of the sunlight upon the snow produces a decided retinal irritation, it manifests its chief symptoms upon the eye by producing a severe conjunctivitis with sometimes a diffuse keratitis and ulcers of the cornea. It rarely leaves any bad results.

The effect of bright electric light upon the eye has also been investigated and the results noted. Just what degree of brilliancy it takes to produce injurious effects upon the eye has not been definitely settled. It is true that the ordinary incandescent electric light seems the best for general illuminating purposes. It is brilliant, produces less heat and therefore less particles of combustion, is steadier than gas in many instances, and is the nearest approach perhaps to the daily sunlight. However, I must say that experience in the use of incandescent light and the Welsbach gaslight with proper shading has influenced me into a preference for the latter. Of course, the latter is more troublesome to keep and therefore has its disadvantages, but when subdued by the use of white shades it certainly makes a most excellent light by which to work. Personally I have used this light for years and now prefer it to any other. Hartridge of London, in an article published in the *British Medical Journal*, 1892, on "The Effect of Electric Light Upon the Eyes," says that no bad results have ever been observed in the eyes from the ordinary use of the incandescent light. Although since this publication I have seen no other reports to the contrary, personal observation prevents me from agreeing with the author referred to. A case recently under my observation could be attributed to no other cause. Mr. H., aged twenty-four years, night-clerk in a hotel, consulted me last February on account of a slight irritation in his left eye. History was as follows: Physically he was a perfect specimen of manhood. He worked every night as bookkeeper and clerk under the constant glare of the incandescent electric lights and slept during the day. Up to this time he had never had any trouble with his eyes; he gave absolutely no history of syphilis nor could any signs be found on the closest examination; he had never been sick a day in his life, nor had he ever had the slightest touch of rheumatism, and never felt better than at present.

On examination the left eye showed contracted pupil, but no more than the right. It did not respond to light. There was only the faintest zone of circumcorneal congestion. Vision was normal but photophobia was present. Right eye was normal. On using atropine in the left eye an incipient iritis was readily diagnosed. It was impossible to dilate the pupil *ad maximum*, although there seemed to be no points of adhesion. The iritic muscles appeared perfectly torpid.

The case proved to be one of long treatment, although at no time were the objective or subjective symptoms severe. Nothing was used but atropine solutions, hot fomentations and blisters to the temples. Leeches finally produced a most rapid amelioration of the symptoms. In this case, there was no doubt in my mind that the attack must be attributed to the electric light. He worked for hours every night with an incandes-

cent drop-light just in front and to the left, so that there was a constant glimmer, especially in the left eye. There was never any trouble with the right eye. Since that time he has had no further trouble as he was transferred after recovery to day-duty.

During the last few years I have had under my care for ocular troubles a number of young ladies boarding in a large school where incandescent lights were used. In some cases I have had to order a cessation from school work, and in other cases I have substituted a student's lamp for the electric light with the most gratifying results. My experience has been that these incandescent electric lights are not suitable for a light by which to do constant work.

Hewitt in the *British Medical Journal*, 1893, calls attention to a condition of the eye designated as electric ophthalmia. The symptoms of this disease are said to be the same as those of snow-blindness, *viz.*, swollen lids and congested conjunctivæ, later followed by a muco-purulent discharge. This condition is usually found among those employed in electric welding operations, less frequently among those who use arc lights. Several cases have been reported of blinding or dazzling of the retina through intense flashes of lightning which show some similarity to those caused by electricity.

As I have said Professor Haab of Zurich was one of the first to call attention to changes in the retina, especially in and around the macular region from traumatic and constitutional causes, in an article read before the Seventh International Congress at Heidelberg, 1888, and in 1889 E. Meyer from the same clinic continued the study of the subject. These two writers discussed more in detail the vulnerability of the macular region to various causes rather than to any particular one of traumatic origin. Their subsequent writings seem more of a clinical demonstration of their views set forth. In 1894 Dr. E. C. Rivers published a very interesting case in Knapp's *Archives* on "Injury to the Eyes from Heavy Charge of Electricity." This case condensed is as follows: H. E., aged twenty-five years, employed as an engineer in the motor-house of the Denver Car Company, accidentally made a short circuit by means of a small wrench in his hands, causing the full 500 volts to pass through his arm and out at the wrench, accompanied by a loud report and a very intense flash of light. The patient was stunned and immediately had severe pain in the eyes. Rivers saw the patient one hour after the accident and found the following condition present: Face, eyebrows and lids, neck and hand badly burned. On examining the eyes the conjunctiva was found strongly congested and the cornea of both eyes almost opaque. Vision equalled perception of light. Under the use of atropine, castor-oil, and dry aseptic cloths, the eyes progressed well. On the third day the whole eschar on the cornea was thrown off and this being only the epithelial membrane the remainder was left clear. A few days later L.E., vision equalled 20/40; R.E., vision equalled 20/100. The ophthalmoscope showed the media clear. The retina in the right eye looked hazy. Visual fields were normal for all colors. Six months later the patient reported that he still suffered from photophobia and had to wear colored glasses. He was also compelled to look very intently in order to see small objects. In my own cases the flash was not near enough to produce burning of the tissues.

Dr. L. D. Broose of Evansville, Ind., has reported two cases of retinal irritation from electric flashes which correspond in detail with my own: J. H., aged twenty-four years, an employee of the electric street railroad, accidentally received a shock from one of the trolley wires and at the same time the eyes were subjected to a very intense flash of light. When seen five hours later the conjunctival vessels were found injected, the eyes suffused with tears, pupils contracted and the patient suffering intense pain. None of the parts were burned. Patient was directed to stay in a darkened room and a two-per-cent. solution of cocaine was used in both eyes. In twenty-four hours he was able to resume work. F. W., aged twenty-three years, also an employee of an electric street railroad, struck a live wire with a file which he held in his hand and immediately there was an intense flash and the patient was rendered unconscious, this latter condition persisting but a short time. When seen a few hours later the patient was complaining of a severe pain in his eyes. The balls and lids were found markedly congested; pupils contracted. He was treated in the same manner as the first patient and in five days the patient was able to resume work. The ophthalmoscope showed nothing abnormal. No mention was made of the field of vision.

Professor Haab discusses this subject and reports another case, the clinical study of which presents some features of interest. As this article has not appeared in English, I will take the liberty of making an abstract report. H. W., aged thirty-four years, machinist, consulted Professor Haab on August 9, 1895, concerning his eye which had received a flash of light from a dynamo of sixty amperes. He came the same morning, immediately after the injury, because of the dimness of vision noticed, especially in the lower field. He was stunned by the flash of light, which was very near the eyes, and for a few moments could see nothing. The right eye being nearer to the dynamo than the left, it was the most affected. The pain was severe in both as if needles were sticking in them. There was only a slight irritation with some hyperemia of the conjunctiva of the right eye. Both pupils were contracted, the right more than the left. The irides appeared normal, R.E., vision equalled 3/10; no improvement with glasses; L.E., vision equalled normal. The ophthalmoscope showed nothing abnormal. On the next day the condition was decidedly better. R.E., vision equalled 3/10: w. = 0.5 D. equalled 3/6. On dilating the

pupil the left eye showed nothing abnormal. In the right eye a very interesting condition was present: (1) Extending over the whole macular region there was a very fine, milky discoloration so that the normal granular appearance was absent. In the deepest part of the macular center the discoloration was slightly less. A similar discoloration was nowhere present in the retina. (2) Running along the periphery of the retina could be seen a few yellowish-white spots of irregular form and size about once or twice as broad as a large branch of the central artery. Some spots existed also below the fovea, the latter being quite fine. In the middle of the fovea two small bright specks were found. Whether these small spots were in the retina or in the pigment epithelium could not be discovered. However, they were nowhere as white as those found in diabetes or albuminuria. Along the retinal vessels and on the papilla nothing abnormal could be found. The lens and vitreous were normal. The treatment consisted in absolute rest and the wearing of dark glasses. August 16th, R.E., vision 3/6 w. = 1 D; L.E., vision normal. The macular is slightly opaque. October 13th. The eye appeared normal. No signs of cataract.

These cases, as well as the subject itself, are of interest to the ophthalmologist as affording clinical data upon which to base a prognosis whenever such accidents should come under his care. Since electricity has become so universal in domestic use, accidents referable to it as a cause will necessarily be more common. The prognosis in all diseased conditions is determined by clinical experience, and hence the greater the number of cases reported the more certainty there is for a basis of deduction. The writer of this article does not lay claim to any original investigation, but purposes to bring forth from others their own personal experience. In the study of the cases reported there are many points of interest involved and chief among them as to whether the changes produced in the eye had a clinical or traumatic basis. This point certainly opens up an interesting field for investigation. Another point to be noticed was the universal presence of two symptoms in all cases, *viz.*: (1) The contraction of the pupil from the retinal irritation which was so strong that it persisted for several days. (2) The pain present always coming on several hours after the accident.

The action of electric flashes upon the eye is always classed as traumatic. Widmark has made some extended researches as to ocular trouble due to exposure to electric lights. From these he concludes that such are produced by a direct irritation of the parts affected, and that this irritation is produced almost exclusively by the ultraviolet rays, which as is known exert a similar influence upon the skin. This would raise an interesting question as to whether this same cause was not also the active one in the production of those skin lesions following exposure to the X-ray. Widmark has also found that such rays can also produce striated opacities of the lens. If such then be the case, it is justifiable to conclude that domestic lights are injurious to the eyes in proportion to the amount of the ultraviolet rays they contain. According to my own observation the Welsbach gas light has proven more satisfactory and less injurious as a light by which we may read and work than any other of which I have had any experience. It might be of interest to some of you to know the *modus operandi* of the Welsbach light, a name given after Baron Auer von Welsbach who first discovered the principle of such illumination. This light is produced, as you know, by ignited gas passing through a thin conical veil-like body called a mantle. It is on the order of the calcium illuminator. This mantle by being heated radiates a steady strong white light. The chief point is therefore in the construction of these mantles. A recent writer tells us that the mantles are made by "saturating a fabric with a solution of rare mineral earths and then burning out the fabric leaving a delicate crystalline skelcton." The rare earths considered most effective are thorium and cerium and they are contained in mineral mozarite, deposits of which, from having been almost worthless thirty years ago, have now attained great value. The writer also adds that "attempts have been made recently to make mantles on another than the Welsbach principle of saturating a fabric and then burning it out, namely, by making the ingredients into a paste with some gummy substance, drawing it out into threads and then weaving these into fabric, and burning it out as before." In conclusion, I would say that when the Welsbach is used for reading purposes there should always be an under shade, preferably white, so the intensity of the light may be mitigated.

GRAVES' THYROID DISEASE.[1]

By O. T. OSBORNE, M.A., M.D.,
OF NEW HAVEN, CONN.;

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS AT YALE MEDICAL SCHOOL.

History.—In 1835 Graves of Dublin first described this disease and in 1840 Basedow in Germany again described it. Ever since the disease has been known by the names of these writers or under the name of exophthalmic goiter. I believe that it is always a disadvantage to medical nomenclature to use a writer's or investigator's name to denote a disease or symptom, but it has this undoubted advantage, in that it does not declare for any specific pathology or etiology for the condition. On the other hand, I believe that the much used term, exophthalmic goiter, is a positive misnomer.

In the first place, we can have the symptoms of increased secretion of the thyroid gland without any apparent enlargement of the thyroid. Secondly, we can have an enlarged thyroid with

[1] Read before the Section on Practice of Medicine of the American Medical Association, Atlantic City, N. J., June 5-8, 1900.

symptoms of hypersecretion without any exophthalmos. And thirdly, we can have exophthalmos without an enlarged thyroid and without symptoms of its hypersecretion. Therefore, I suggest the name of Graves' thyroid disease as one both distinctive and descriptive.

Frequency.—There seems to be a widely varying opinion as to the frequency of this disease, the majority of reporters believing that the disease is rare, while a large minority believe that it is very rare and a small minority state that the disease is frequent.[1] I have come to the conclusion that as far as the majority of practitioners are concerned the disease is rare, but that physicians in large centers of population will naturally see a good many cases of a disease which is so hard to cure and so troublesome in its symptoms. Consequently these practitioners see enough cases of Graves' disease to believe that it is frequent. Very rare I believe it is not.

Etiology.—There is no question of the great preponderance of this disease in the female as compared with the male, one writer even going so far as to state that "subjects of this disease are almost without exception women."[2] Dana[3] states that eighty per cent. of the cases are in women and Oppenheimer[4] that the ratio of women to men is twelve to one.

This thyroid disease probably never occurs in infancy and is very rare in early childhood and old age. It is preeminently a disease of young adult life and from the reports based upon the observations of forty observers the vast majority of cases occur between the ages of twenty-five and thirty-five and nearly all cases between the ages of twenty and forty.

Consequently in studying the etiology of a disease which occurs with such great preponderance in women and during the most active part of their sexual life we can but wonder what insidious relationship exists between the ovaries or the uterus and the thyroid gland. This question is answered by Freund,[5] who says that the thyroid gland is always congested and swollen during pregnancy and during menstruation. He also says that when there is continued or severe irritation of the uterus there will become a permanent enlargement of the thyroid. This accounts for the greater frequency of this disease in women than in men, as a gland which so frequently physiologically hypersecretes could easily be stimulated or irritated to more or less lasting increased activity.

The weight of opinion seems to be that this disease is not hereditary, although some reporters[6] have noted hereditary tendencies. I have noted several cases which will bear out the opinion of Dr. Charles Dana,[7] who believes that Graves' disease is not hereditary except in certain families where there is a tendency to goiter. It seems to be both an individual and a family disease, individual in that there may be but one case in a family and that it is not hereditary, but family in that its most frequent cause, intense emotion, is undoubtedly most liable to occur in neurotic families. Thus several members of such a family may show different symptoms of increased thyroid secretion with but one of them, perhaps, developing an actual Graves' disease; in fact, neurotic, as we use it, means emotional, excitable and mentally active.

Twenty of the forty observers reporting on the question place violent emotion as the most frequent predisposing cause. Heart lesions are placed as the next most frequent cause, and ordinary goiter and prolonged coughs are thought by several to be frequent causes of exophthalmic goiter.

We cannot better understand the etiology and symptoms of this disease than by studying the condition of thyroid extirpation and the symptoms of thyroid feeding.

Physiology of the Thyroid Gland.—That the thyroid gland furnishes an internal secretion necessary to the health of the organism is proved by the fact that absence of this gland or its lack of development in infancy produces the condition of cretinism, by the fact that atrophy of this gland causes the condition of myxedema, and, finally, by the fact that complete thyroidectomy causes operative myxedema and death.

Cretinism is a condition of impaired body and mental development, with gross, heavy features, edematous condition of the skin and harsh epidermis, while myxedema causes mental hebetude, thickening of the dermal tissues, and mucous edemas, especially of the face and hands. Operative myxedema, or cachexia thyreopriva, shows the ordinary symptoms of myxedema but much more intense, with tremors, convulsions, decreased cutaneous sensibility, dried skin and falling out of the hair. All of these three conditions, namely, cretinism, myxedema and operative myxedema, are cured and the symptoms kept in abeyance by thyroid feeding.

If thyroid extract or substance is fed to the normal individual in small doses it causes no evident symptoms. In good sized doses, or in small doses long continued, it causes loss of weight, palpitation, dizziness, sweating, tremors, signs of cardiac weakness and general debility, with nervousness and perhaps insomnia; in other words, the very symptoms which occur in exophthalmic goiter, which symptoms I believe are caused by hypersecretion of the thyroid. Also during the exacerbation of a Graves' disease the symptoms are all aggravated by feeding thyroid substance.

The active secretion of the thyroid gland seems to be the colloid material, which is a proteid substance containing phosphorus and iodine, the latter of which was discovered by Baumann in 1895. This gland is probably the only organ of the body that normally contains iodine and the average adult thyroid contains about .004 of this element. The gastric juice does not impair the action of the thyroid substance, though it undoubtedly breaks it up into several new combinations.

Physiologists have found a substance in this

gland which causes dilatation of the blood-vessels and a lowering of the blood-pressure. The gland seems to have the function of regulating the heart and vasomotor system, and it has been found that in absence of thyroid secretion the regulation of the loss of temperature is impaired, in other words, a vasomotor ataxia is present. It is quite possible that the thyroid and the suprarenal glands have the thermostatic power of regulating the temperature.

The thyroid also seems to have a great deal to do with the regulation of the development of connective tissue, for the less this secretion, apparently the greater the connective tissue development.

Examination of the excretion of obese individuals during the feeding of thyroids has shown that the metabolism of the body is increased as proved by an increased nitrogen, sodium chloride and phosphorus loss. Thyroid substance also acts as a diuretic, perhaps because it tends to increase the formation of urea, which is diuretic.

It is interesting to note that one observer, Bettmann,[8] has noted that thyroid feeding can produce an alimentary glycosuria, and we know that glycosuria is a frequent complication of Graves' disease or hypersecretion of the thyroid.

To sum up the physiological action of the thyroid, this secretion seems necessary for the proper equanimity of the central nervous system and perhaps nutrition and development of it; to the proper quantity of mucin that shall appear in the tissues, principally the connective tissues; to the proper organization of phosphorus for the assimilation into bone salts; and by its vasodilator power to properly regulate the peripheral circulation, thus regulating the heat loss and the normal insensible perspiration of the skin, which if disturbed shows on the one hand in the drying of the skin in myxedema, and on the other hand in the increased sweating in Graves' thyroid disease. Also this gland seems to have some power of regulating the rapidity of the cardiac contractions. It is probably easily excited to hypersecretion temporarily by emotion, and we know it to be normally enlarged and hypersecreting during menstruation and pregnancy.

Symptomatology.—To study the symptoms of this disease I would divide the course into periods, *viz.*, (1) the prethyroid period; (2) incipient symptoms; (3) the symptoms during exacerbation; (4) defervescence or, in cases that do not get well, the complications that cause death.

1. According to my belief as to the etiology of this disease, I cannot agree with one-third of those reporting cases who have stated that the onset was rapid. Neither can I believe that there were no symptoms before "the violent emotion" which precipitated the active symptoms. I believe that there is a long period of irritability of this gland as shown by neurotic symptoms, possibly a goiter which is irritating the rest of the gland, possibly some uterine disease or inflammation, or irritation, if the patient is a woman. I believe there have been repeated emotional disturbances, perhaps as far as symptoms go, well tolerated, but all of which conditions have given a chronic stimulation to the thyroid gland until the active symptoms, exophthalmic goiter, are present. Two-thirds of the cases of which reports have been sent to me have shown just this slow development and did not even apparently begin rapidly. The other third began their active symptoms rapidly; but I have not a doubt that the gland had been hypersecreting for a long time before. The apparent rapid onset in these cases due to some violent emotion is the last stimulant to a gland that has been so many times irritated as to finally lose its power of cessation of hyperactivity, and has lost its regulator, so to speak.

In order to diagnose these premonitory symptoms or signs of increased thyroid secretion, we must of course turn to the physiological action of thyroid secretion, namely, its tendency to produce palpitation, sleeplessness, headaches not assignable to any one cause, hot flashes, tendency to perspire readily due to dilatation of the peripheral blood-vessels, nervous irritability and excitability, and, if with these conditions we have continued uterine disturbance, we can state that this woman is in danger of developing Graves' thyroid disease. Doubtless many cases are being treated for functional disturbances in which we have a mildly increased thyroid secretion, not enough, perhaps, to give exophthalmos or an enlarged gland.

2. What are the initial symptoms of an actual developing Graves' disease? I find by my reports that the first symptoms of well-marked cases were just the symptoms to which we have referred, namely, palpitation and enlargement of the thyroid and nervous irritability; and these are the symptoms which the patients themselves have noted as the first objective signs of their disease. This simply means that in the patient who comes complaining of severe palpitation, nervous excitability and irritability, we should examine the condition of the thyroid and for diagnostic purposes feed her for a week on thyroid extract. If she is worse, our diagnosis of pending exophthalmic goiter seems to me to be probable.

3. Classically, we know the three symptoms of an established case of Graves' disease to be exophthalmos, enlarged thyroid and palpitation of the heart. Any one of the three legs of this tripod may be absent, but they generally are all present. The exophthalmos is generally of both eyes, but rarely one eye may be affected and that is generally the right. It is generally constantly present, may be occasionally present, is rarely altogether absent, in the majority of cases is mild in degree, but quite frequently is excessive. This forward projection of the eyeball is probably due to the overfilled blood-vessels in the back of the orbit. The so-called von Graefe symptom is the

inability of the upper eyelid to follow the eye when the patient looks down, due to the bulging forward of the eyeball. Stellwag's sign is the widening of the palpebral fissures, due to retraction of the upper lid, combined with infrequent winking. There may be a retraction of the lower lid and rarely ptosis or weakness of the ocular muscles and therefore inability to converge the eyes, Möbius' sign.

The thyroid gland may be enlarged as a whole, but generally only half of it is enlarged and that on the right side. It varies in size from time to time, but is rarely large enough to cause symptoms from pressure. There may be developed a cystic degeneration and the appearance of a regular goiter, but the rest of the gland is hypertrophied and hypersecreting.

Palpitation is of frequent occurrence and in nearly half the cases is severe. In the rare cases in which palpitation is mild in degree, it is probably in the later stage of the disease, that is, the stage of recovery. The rapidity of the pulse in fully developed cases varies, but averages one hundred and twenty beats to the minute in the majority of reported cases. It may be irregular, is rarely intermittent, but is often a fair pulse. Actual valvular disease as shown by the physical signs seems to be rare, but a large number of cases show hypertrophy of the heart and not a few dilatation. The next most constant symptom is tremor, rapid and involuntary, and most frequent in the hands and arms. General headache, insomnia, and mental depression are almost constant symptoms. Hysteria is present in about one-third of the reported cases and melancholia is certainly not infrequent. Signs of vasomotor ataxia are constantly present, such as vertigo, hot flashes, sweating, cold sensations, sudden paleness, local hyperemias, and, in some few cases, recurrent epistaxis. Pain, in addition to the headache, is most frequently referred to the eyes, next most frequently to the neck, and often to the ears. Dyspnea is of frequent occurrence and generally occurs with palpitation, both of which may be due to any nervous excitation. Cough is often present, probably largely due to circulatory disturbances. The other associated symptoms of this disease can be referred to the nervous condition of the patient or to the etiological cause of the disease, namely, hypersecretion of the thyroid. It is interesting to note that in a large number of cases in women there are menstrual disturbances and generally increased loss of blood. With the frequent palpitation, headache and sleeplessness, we could but expect the digestive disturbances, such as loss of appetite and consequent constipation, or in some cases diarrhea and perhaps vomiting. Most cases during the exacerbation, and I am inclined to think almost all cases, will show a loss of weight, and if the urine were carefully examined we would probably find a daily increased loss of nitrogen. As to how much muscular weakness there will be depends upon the rapidity of the loss of weight, the frequency of the palpitation and the condition of the nutrition. Some patients complain bitterly of the weakness of their legs, even falling down.

The diminished electrical resistance of the skin which seems to be quite a constant symptom when tested, may be due to two causes, namely, to the fact that the blood-vessels of the skin are more dilated than normally and therefore the skin shows less resistance, or that it may be due to the increased excitability of the central nervous system. Malnutrition of the skin may be shown by the falling out of the hair; there may be bronzing of different parts of the body, or there may be vitiligo. Sometimes polyuria is present, and a glycosuria or an albuminuria may develop. If there is polyuria or much sweating, the patient will complain of thirst. Added to the above, we may have all kinds of eye, ear and heart symptoms.

4. The duration of the disease may be from two to ten years or more. If the case does not do well and is to end in death, the complications that will bring this end about are diabetes (one of the most frequent), actual cardiac disease, and possibly a condition of progressive muscular debility or neurasthenia. The frequency of diabetes in this disease of an internal secreting gland is interesting in that other glands furnishing an internal secretion often cause diabetes when they become diseased. This is certainly true of the pancreas, for this gland furnishes an internal secretion, and it is certainly true of acromegaly with disordered pituitary secretion, unless here, too, it is the thyroid that is in trouble.

Cases that have lasted more than five years do not seem to tend to recovery. Cardiac weakness and insufficiency with edemas, passive congestions and albuminurias may occur even to a fatal degree. The severe nervous complications of melancholia or mania, chorea, etc., are rare, although hysteria is a more or less constant symptom. Cases that get well generally do so in two or three years, perhaps sooner, with a gradual amelioration of all the symptoms. It is difficult to estimate the number of cases that die and the number of cases that get well, but a considerable majority recover. Probably not more than ten per cent. die of this disease *per se*, the others die as a result of complications. Cases that get well etiologically do so from the gradual diminution of the secretion of the thyroid. This might naturally occur at the menopause in women.

Pathology.—Time will not permit me to discuss or to mention arguments for and against the various theories which have been offered as to the pathology of exophthalmic goiter. I refer to the cardiac theory, to the sympathetic-disease theory, and to the vasomotor neurasthenia or ataxic condition, which last I consider the result and not the cause of the disease. Briefly, I believe the symptoms to be caused by a hypersecretion of the thyroid gland. This hypersecretion carries with it of course all of the physiological actions of this product, two of which we understand, but we do not know how many

more there are. These two elements of this secretion will cause most of the symptoms present in exophthalmic goiter. First we have the vasodilator substance which we know dilates the peripheral blood-vessels and probably the abdominal vessels, in the former case causing the hot flashes and the sweating, and by filling the blood-vessels of the skin is at least part of the cause of the diminished electrical resistance, although as above stated another cause may be the excitation of the central nervous system. That this dilated condition of the peripheral blood-vessels is not continuous, which would be a condition of paralysis, is shown by the sudden coldness of the surface and chilly sensations, in other words, an ataxic condition of the vasomotor center. This irregular opening and shutting of the blood-vessels is at least one cause of the cerebral irritation giving insomnia and headache, both of which if neglected may lead not only to hysteria, but even melancholia or more serious cerebral disturbance.

Whether due to the diminished peripheral resistance, to the vasodilatation, or, perhaps, to some unknown irritation which this hypersecretion causes to the cardiac nervous mechanism, or a partial paralysis of the inhibitory mechanism, the heart begins to beat very rapidly and tachycardia is a frequent symptom. According to Dana, the rapid heart is probably due to impairment of the inhibitory fibers of the spinal accessory nerve. That there is thickening of some of the blood-vessels, seems to be proved and perhaps is as difficult to account for as the thickening of the blood-vessels in acromegaly. Where the thyroid gland has been found to have its connective tissue increased, I believe the patient has undoubtedly died of an intercurrent disease and the real exophthalmic condition was curing itself. When we consider the number of cases that get well under almost any treatment, we can only infer that the hypersecretion becomes gradually diminished and that the gland itself becomes worn out; I believe it is perfectly possible to have connective tissue form in the gland and the degeneration of the parenchyma go so far as to give diminished secretion and putting on of weight and possibly a partial myxedema.

A heart cannot beat rapidly for any length of time without its muscular tissue becoming weakened, and then any exertion or any extra work thrown upon it will cause a dilatation and the consequent results and symptoms of incompetency, namely, maldigestion of all kinds, passive hyperemia of the liver, and passive hyperemia of the kidneys with perhaps albuminuria.

Another increased element in this hypersecretion is that containing iodine. One function of this substance is to increase the nitrogenous, sodium chloride, and phosphoric acid waste. The body loses weight in an active case of exophthalmic goiter, and we are very liable to have with the increased urea output a diuretic action and polyuria. Whether from this increased nitrogenous metabolism or from some other cause we may have such dietetic and glandular disturbances as diabetes as a frequent complication, and whether these elements which we have described can account for the intense cerebral excitation which occurs, are of course questions. Whether or not there is another element in this thyroid secretion which may be utilized by the system when in normal amount, but when in excessive amount produces a toxic blood state, as held by Möbius, I am not ready to state, although there are a good many believers in the theory that something from the thyroid in this condition irritates the central nervous system.

In regard to the histology[9] of the gland itself in exophthalmic goiter, and I say histology instead of pathology because the typical gland in exophthalmic goiter is an hypertrophy or a condition denoting hyperactivity similar to the developing thyroid or to a mammary gland during lactation. That there have been pathological[10] findings in thyroid glands in these cases does not militate against the theory of normal hypertrophy, because it has been shown that a diseased gland, as colloid degeneration or an injury to some portion of it, or a goiter, can cause the rest of the gland to hypersecrete.

Here I would like to offer some thoughts which occur to me as worthy of discussion. In the first place, about eighty per cent. of all cases of exophthalmic goiter occur in women and between the ages of twenty and forty, while about eighty per cent. of all cases of myxedema also occur in women but between the ages of forty and fifty.[11] The exophthalmic goiter, due to hypersecretion, occurs during the active child-bearing period when the thyroid normally periodically hypersecretes. The myxedema, due to absence of thyroid secretion, occurs at the time of the menopause. Next, it is but a short step to infer that the hot flashes, nervousness, palpitation and cerebral disturbances occurring at the menopause or during that period are due to disturbed thyroid function. A primary hypersecretion before the thyroid atrophies would cause the profuse hemorrhages. As the thyroid atrophies normally after middle life, is its modified function possibly a determining cause of the menopause? Also, is its diminished secretion not one of the causes of the putting on of weight in women after the menopause? Also, as suggested by Bell,[12] who says that carcinoma of the uterus is a sign of epithelial degeneration and hence his treatment with thyroid feeding, is the diminished thyroid secretion the cause of the frequency of cancer after middle life, especially of cancer of the uterus after the menopause? Also, would we find that cancers occurring in young people are in cases in which the thyroid is undersecreting?

Diagnosis.—A well-marked case of Graves' thyroid disease is easy of diagnosis and cannot well be confounded with any other condition. The three cardinal symptoms of enlargement of the thyroid, exophthalmos, and tachycardia, occurring synchronously and with the fourth im-

portant symptom of tremor, give the diagnosis almost at a glance. Believing as I do that this disease is due to hypersecretion of the thyroid gland, a diagnosis of hypersecretion of this gland should be made before the radical symptoms have developed.

Hence, as above stated under the premonitory signs and early clinical history, headaches, sleeplessness, hot flashes, unexplainable sweating, nervousness, tremors, and irregular cardiac action, all or any of them might have increased thyroid secretion as a cause. Of course any tumor, whether a simple goiter or other growth, could press on the vagus or sympathetic and cause some of the symptoms of exophthalmic goiter. These conditions are generally easily diagnosed.

Prognosis.—As to the probable duration of a given case, it is practically impossible to make any estimate. The family tendency to neuroses or the previous neurotic symptoms of a case, and the rapidity of onset of apparent symptoms may cause a fair estimate as to prognosis of recovery. It is better where there is no family tendency to neuroses, where the patient has not previously had any nervous symptoms, and where the onset was apparently rather rapid. Well developed cases may recover in from one to five years. Theoretically, the older the individual in whom it develops, the sooner may recovery be expected. The percentage of cases that entirely recover is variously estimated; perhaps from twenty to thirty per cent. can be expected to get well, although some of these are certainly liable to relapses. Perhaps it is not unfair to state that seventy-five per cent. of all cases can be relieved and rendered more comfortable, this depending of course upon the length of time the symptoms have been present when the case comes under observation. In all probability, if all cases were treated to the best of our ability in the beginning, the majority would get well. By the time a case comes under observation there is likely to be a permanently impaired heart or an almost irreparable neurotic or neurasthenic condition, with possibly metabolic disorders, such as diabetes. Perhaps from ten to twenty per cent. of the cases die from complications directly attributable to this disease. Burr[13] says that the disease is more fatal in men than in women. Pregnancy occurring in women in this disease seems to cause an amelioration of the symptoms, probably due to the fact that this condition requires and uses up a certain amount of extra thyroid secretion. The symptoms are also better during menstruation.

Persistent tachycardia cannot fail to cause weakness of the cardiac muscle and dilatation sooner or later. Likewise hard work or labor will tend to hasten this cardiac weakness, and then all of the symptoms of cardiac dilatation occur. Progressive loss of weight, showing the nitrogenous waste that is going on, produces neurasthenia and, finally, permanent invalidism. Diabetes is a serious complication.

Treatment.—In the first place can this disease, or does this disease, cure itself? I believe that it does. Hence the lauding of so many different methods of treatment as giving good results. Moreover, as this disease tends to show temporary improvement, we must take into consideration this fact in estimating the value of any special treatment. If we believe this disease is caused by a hypersecretion of the thyroid gland, we must also believe that cases recover by the diminution of the amount of this secretion, possibly by atrophy of, or connective tissue-formation in, the gland. Anything that will take up or utilize this secretion, as pregnancy, will improve the case; and as this gland naturally atrophies in old age, age would certainly be a natural cure. I believe that in suspected cases or before the complete development of the case, if we have reason to believe that there is a hypersecretion of the thyroid, the feeding of thyroid gland should increase the symptoms. With our diagnosis thus made we would know how to treat the case. If the symptoms are thoroughly developed, the indications for treatment are: (1) To reduce or stop, if possible, this hypersecretion of the thyroid gland. (2) To prevent complications. (3) To strengthen and build up the system already worn out or debilitated.

In the first place, anything that will tend to increase the outflow or output of this secretion or stimulate the gland to further secretion can do nothing but harm. This is often seen by applying electricity locally, or by considerable manipulation of the gland, or by the taking of alcohol, or by anything that tends to further dilate the blood-vessels, stimulate the heart, or to irritate the gland. Anything that quiets the circulatory system without putting more blood at a greater tension into the head will do good. This does not mean that every case of cardiac palpitation in exophthalmic goiter should have digitalis or some equivalent, because I believe that in the cases without dilatation or without real cardiac weakness these drugs will often cause more headache and more cerebral trouble than before. With cardiac dilatation digitalis or its equivalent always does good, but strophanthus often acts more satisfactorily. It can readily be seen that with this treatment we are symptomatically treating the case, that is, combating the rapid heart and the dilated condition of the vessels without eradicating the cause of this condition. Our strongest adjuvant in bringing about this quiet heart-action and the diminished irritation and excitability and therefore hypersecretion of the thyroid is absolute rest in bed, mental as well as physical rest, for anything that excites this easily excitable heart will add to the unpleasant symptoms.

Now, as to any possible treatment to actually prevent this gland from hypersecreting, we naturally turn first to organic extracts. I do not believe that thyroid extract can do anything but harm except in cases in which the active stage of exophthalmic goiter is passed and a stage of

diminished secretion and possibly mild myxedema is present. We have all seen these cases of exophthalmic goiter, and I have one now under observation that is thriving on thyroid extract, whereas all my other cases are made worse by it. The patient has some palpitation of the heart, and an enlarged thyroid, but no headache; she is growing stout, sleeps well, but is very weak. Hence, I believe if there is any value in the use of thyroid extract in the treatment of exophthalmic goiter, it is at a time when the gland is the seat of sufficient connective tissue or colloid degeneration to impair its secretory functions.

Recently Lanz[14] of Berne has experimented with the serum of animals deprived of their thyroids, which serum consequently, he says, contains the toxic substances capable of neutralizing thyroidal hypersecretion. On this theory he gave to three patients the milk from goats deprived of their thyroid glands with good results.

Theoretically, the suprarenal extract or substance should be good treatment for exophthalmic goiter where the vasodilating element of the thyroid is increased, suprarenal being a vasocontractor, but Moore[15] and Purinton have proved that this vasocontracting element of the suprarenal is not absorbed by the stomach; hence, if this treatment does any good in hypersecretion of the thyroid, it is some other and not the vasocontracting element. Therefore, I cannot but believe that clinicians who have had much success with suprarenal treatment in Graves' disease happened to give this substance at a time when the symptoms were ameliorating. Personally, I have seen absolutely no results from the use of suprarenal extract in this disease.

The thymus gland treatment of exophthalmic goiter is beginning to have a large backing, and in several of my cases I believe that the whole condition has been improved by this treatment, one or two tablets being given daily. Perhaps one of the first in this country to recommend thymus treatment in this disease was Dr. S. Solis-Cohen.[16] He reported that he had treated twelve cases of exophthalmic goiter with thymus gland. Whether this gland slows up, or diminishes, or combats the secretion of the thyroid, we do not know. It certainly does not contain iodine.

Other drugs which will diminish the secretion of this gland, but unfortunately at the same time upset the secretion of other glands, are morphine, codeine, belladonna, and hyoscyamus or the alkaloids of the latter. Good results have undoubtedly been obtained from any of these four drugs because of the diminished secretion. Theoretically, were we to use these drugs for this object morphine or codeine would be most indicated as not only diminishing the secretion but quieting the heart. Hyoscyamus and belladonna, especially the latter, must excite the heart while they are stopping the secretion of the thyroid, and the discomfort which results from pushing belladonna or hyoscyamus cannot recommend them as good treatment. Morphine will produce more or less of a habit, and except to tide over a certain period of exacerbation, is not often justifiable. Codeine will cause less general disturbance, but is less effective.

The immense amount of restlessness, cerebral irritation, excitation and hyperemia may compel the administration of bromides. They will always do some good, whether by preventing the hyperemia of the brain, or whether by combating the irritation of the nervous system caused by the toxic substances formed in such large amount by the thyroid, we do not know. It is purely symptomatic treatment, and, if pushed to any great extent, can cause nothing but debility.

The iodide treatment has many advocates. It probably does little if any good in small doses and in large doses can but increase the waste of the tissues and, if it does any specific good, it must be by causing atrophy of the gland and at the same time must cause atrophy of other glands. Good results have been reported from sodium phosphate, and theoretically this would be compensatory treatment considering the large loss of sodium chloride and P_2O_5 caused by the hypersecretion of the thyroid.

Electricity can only be a part of a general tonic treatment. General faradization can but do good if it does not increase the nervous excitability. Central galvanization of the sympathetic system possibly might do good, and faradization over the gland might possibly ultimately cause a better tone and contraction of the gland, but the stimulant action of the galvanic current locally with the negative pole active would be contraindicated, and with the positive pole active for the purpose of diminishing the blood-supply to the gland would be problematical.

As to operative treatment, I find but few believers in surgical interference with this gland for the ordinary symptoms of exophthalmic goiter. There can be no question of the advisability of removing a portion of the gland if there are pressure symptoms. Theoretically, if we find a cystic growth or colloid degeneration, or some enlargement of some portion of the gland, and such have been proved to be able to so irritate as to cause hypersecretion of the rest of the gland, it would be good treatment to remove that pathological portion. Dr. M. Allen Starr[17] suggests that some of the deaths after operation are caused by the handling of the gland causing an increased absorption of the secretion, thus poisoning the system.

Dana[18] says that he believes in cases that cannot rest or have proper treatment for one or two years the advisability of surgical interference should be considered; otherwise he believes it unjustifiable. Operation however may not completely cure.

To sum up, then, the best treatment in my opinion is rest, thymus extract in small doses, strophanthus, and bromides if must be. Permanent good results should not be expected for from one to two years, and even then relapses may

occur. The condition will always be temporarily better during menstruation and during pregnancy, and probably become permanently cured at the menopause. Complications, such as cardiac dilatation, should be treated concomitantly with the goiter. If diabetes occurs, perhaps codeine is one of the best remedies for both conditions. All uterine disorders should be treated.

THE STATUS OF GENERAL ANESTHESIA IN 1900.

BY M. L. MADURO, M.D.,
OF NEW YORK.

THE anesthetist of to-day not only has at his disposal a considerable number of reliable agents for the production of general anesthesia, but also a great variety of methods for their administration. The custom of employing one anesthetic for all cases must now be regarded as a bygone practice. Our first and most important duty is the selection of the anesthetic which is most free from risk and danger. That brings us to the question which is the safest and most practicable that we possess to-day. The answer is undoubtedly nitrous oxide and ether. Nitrous oxide alone is admitted to be the safest anesthetic, and if its dangerous element, the asphyxial one, were cut out by the combination of oxygen we would here possess the ideal. The complication of apparatus in the latter prevents its more general adoption.

Nitrous oxide and ether is the more practicable and is a safe combination given by an up-to-date apparatus like Bennett's. This instrument has an advantage in the fact that deep asphyxia is avoided by the gas, the ether being turned on from a separate compartment in the same instrument and one is able to grade the amount of the ether. The method is further very rapid, consciousness being lost in an average of seventy seconds and secondary anesthesia being assured within three minutes. The disagreeable preliminary sensations of ether are done away with and the patient is ready for operation within a remarkably short time. Another advantageous feature of this American-made instrument is the fact that it is not bulky like its English competitor.

Nitrous oxide alone will undoubtedly keep its place as the anesthetic in dental work and in operations of short duration. Owing to the greater rapidity with which the phenomena of nitrous oxide make their appearance, there is greater difficulty in arranging them into groups or stages; they nevertheless occur, and a very deep narcosis with absolute loss of rigidity can and does take place; so that if the patient exhibits rigidity during an operation with nitrous oxide it can be put down to the fact of an incomplete narcosis. On the other hand a complete narcosis with gas being a very difficult matter and the asphyxia being alarming, it is always good advice to give the combination of either oxygen or ether where thorough relaxation is desired.

Chloroform is no longer the popular anesthetic it used to be. Experiments have recently proved that there is accompanying its administration a state of vasomotor dilatation which is apt to end in vasomotor paralysis if the drug is either carelessly given or the patient's arteries have at all the slightest tendency to an atheromatous condition. Therefore it is well to place the importance of the vasomotors on a par with the heart and insist on the thorough examination of the vessels with the sphygmograph. The sudden deaths we hear of during chloroform administration are due to this dilatation of the vessels; as described by Hare, the patient will bleed into his own veins. Chloroform in combination with other anesthetics, such as the A.C.E. mixture and the Schleich mixture, is open to the same objection, and it is for this main reason that the latter has been practically discarded since its introduction in 1897. Personally, since I brought it to this country and used it extensively for a year, I have every word of commendation for its use as I never had a bad result. The dissatisfaction that others have experienced can be explained in three ways: (1) Because men who had very little experience judged from a few cases. (2) Because some who might have used it, did not, condemning it on general principles, because they were averse to mixtures. (3) Because experiments were made with the petroleum ether which one observer stated to be lethal on administration to rabbits. The objections were refuted in one way and another, for the combination was only a mixture in the sense that the ether was in excess; the chloroform however was proved to be in perfect solution. Then the fact of its being a poison is true of any anesthetic pushed to the lethal dose; Schleich decidedly disproved its poisonous effects in small doses and held that the reason he used it in his mixture was because he found by experiments on animals that no other ethereal substance could be administered in such large doses without causing serious disturbances. Also it seemed to mitigate the action of the chloroform contained in the mixture and to dilute the other substances without interfering with their action. The new idea brought forth in this anesthetic by Schleich,

which is rational and needs further investigation, is the relation of the boiling point to the temperature of the body. It must be admitted that a narcotic with a boiling point of 15° C. (ethyl chloride) or one which boils at 65° C. (chloroform) must act in different ways on an organism the temperature of which is 38° C. Schleich found that when the boiling-point is higher than the temperature of the body the amount necessary to narcotize is less than when the boiling-point and temperature are equal. Again when the boiling-point is higher than the body temperature the deeper the narcosis. It is clear that a narcotic which rapidly evaporates is rapidly eliminated by the respiratory organs, and one which does not evaporate as quickly, remains longer in the system and becomes more dangerous with prolonged inhalation. I firmly believe that if we can in the near future adapt the principle of the relation of the boiling-point to the temperature of the body with the anesthetics we possess to-day we would see less alarming results. It has certainly been proved possible to change the boiling-point of any anesthetic to the desired degree, but the practice has not been carried out with any single anesthetic like ether which has a boiling-point of 34° C. Ethyl bromide exemplifies the foregoing principle, it possesses the relative degree (38° C.) and as a result we have an anesthetic which is quickest in action of all the other vapors and from the effect of which one recovers most rapidly. Schleich recognized this, but found that its inhalation was accompanied by bad effects due to the bromide. That point can be remedied by careful manufacture and Squibb furnishes the proper product. This anesthetic is especially useful in throat operations; one can obtain its effects in from twenty to forty seconds. The entire quantity, 10 to 20 grams, is poured on the mask, which should be tight-fitting (paper and towel). Note on administration the relaxation of the muscles of the neck and arms; when the pupils of the eyes, which are open, dilate and the conjunctiva begins to suffuse it is time to stop the administration. I shall later have occasion to publish my results in the use of this anesthetic.

Ethyl chloride has been used some in this country, alone and in combination with ether; its patronizers have been few and their reports have not yet been sufficiently encouraging. It is a proper moment here to urge the simplification of apparatus for administering anesthetics, especially that used for nitrous oxide and oxygen, in which I see a great future as the "twentieth century" combination. Who knows that before long the gases will entirely replace the vapors like ether and chloroform, which are no doubt more apt to injure the structures with which they come in contact. At present we must be content with nitrous oxide and ether which when given with the Bennett instrument represents the ideal form of up-to-date anesthesia. It is here noteworthy to remark that the amount of ether used is a great saving over the older methods, 3½ to four ounces sufficing for an operation lasting an hour.

In conclusion, I should like to urge the fact that too much stress cannot be laid on professional anesthetization—the employment of the specialist to administer the anesthetic, for, besides giving the operator, the family, and particularly the patient absolute confidence and comfort, it will certainly tend to efface bad results from unskilled work, thus establishing in this country an incentive to the growth of the "specialists in anesthesia" that will make them a distinct and representative body.

THE PHYSIOLOGY OF SLEEP.

By H. H. STONER, M.D.,
of Rock Rapids, Ia.

Many ingenious theories have been advanced from time to time to explain the peculiar phenomena of sleep. The thyroid gland was at one time believed to possess the function of inducing this state. It was again attributed to pressure by fluid in the ventricles of the brain. Another hypothesis claimed that it was due to blood-pressure at the base of the brain. The theory, however, which at the present time claims the greatest number of advocates, is the cerebral anemia theory. During the period of sleep the brain is observed to contain much less blood than during the waking state, and investigators have rashly jumped to the conclusion that inasmuch as cerebral anemia and the period of sleep are coincident the phenomena of sleep might be rationally attributed to the diminished blood-supply.

The erroneousness of this conclusion is evident in those who have lost vast quantities of blood. Here the brain, as well as every other organ of the body, is highly anemic and yet there is no disposition on the part of the subject to sleep. On the contrary he exhibits every aspect of restlessness; he tosses from side to side in his bed; his eyes stare as in delirium; he moves his limbs about constantly; drops of perspiration stand out on his body and he feels that death is impending. If a diminished quantity of blood in the brain is the cause of sleep such a patient should feel a sense of drowsiness instead of the symptoms above described.

Recent discoveries in the anatomical construction and the physiological action of the nervous system give a clearer insight into the manner in which sleep is produced. Histologists have thought to demonstrate that the processes of associated nerve-cells are not united by anatomical union, but that they lie an appreciable distance apart and are brought into functional relation with each other in consequence of the impact of a stimulus. Thus, an impulse in passing from one nerve-cell to another is not accomplished as a continuous stream; it must halt at

the terminus of the axone process of the initial cell and effect a functional approximation of this process with the dendritic processes of its associated cell. The current may now pass into this secondary cell and so on until in like manner it finally reaches its destination. The nerve-cell with its dendritic and axone processes is now called a neurone. The two sets of processes usually arise from opposite poles of the cell. The dendritic processes take up the stimulus and convey it to the nerve-cell, whence it is transmitted to the axone process. The nerve current now passes along the axone process (also termed axis cylinder) to its terminal arborizations, which by the force of the stimulus is made to extend and come into functional relation with the dendritic processes of the next neurone in order, and so on in like manner is the means provided for the passage of the current over the various segments of the nervous chain. In this way a nervous impulse reaches the psychic elements of the brain.

It is manifest that should the stimulus fail to produce a functional approximation of the processes of associated neurones the current could pass no further and would necessarily fall short of the psychic precincts. The cerebral cortex furnishes the terminus of the sensory and the origin of the motor tracts. There are in the cerebral cortex, however, millions of neurones which are neither strictly sensory nor motor in function. They are the neurones which take part in purely psychic processes. A stimulus falling upon those psychic neurones disarranges the relative position of their processes which results in the production of a feeling which is interpreted as a sensation. Sensation, as every one knows, is the foundation upon which all psychic phenomena are built. Memory, revery, imagination, reason, etc., all have their fountain-head in sensation. Every psychic process being dependent upon sensation for its manifestation, and sensation depending as it does upon the make and break movement of neurones, both sensory and psychic, it becomes readily apparent what result would follow a failure of the processes of these neurones to meet in functional relationship. The *ego* would be utterly oblivious of the surrounding world. The phenomena of sleep I believe to be due to an inability on the part of the processes of the psychic neurones to be extended so as to bridge over the hiatus between them and so to carry on the functions of intellection. This occurs as the result of exhaustion of the cell of the neurone.

Dr. Hodge, in experimenting upon the nervous system of swallows, found that after a hard day's work the histological structure of the nerve-cells of these birds became profoundly modified. The nucleus became shrivelled and displaced, the cytolymph—the food product of the cell—in part or wholly disappeared, and the reticulated meshwork on which depends the mobile qualities of the processes lost its irritability to a degree more or less limited. As a result of these changes the neurone is necessarily incapacitated more or less for the performance of its function.

The cell of a neurone, like any other cell, cannot go on continually in the performance of its function; it must occasionally cease from its labor and repair the loss it has sustained during its period of activity. The period of rest and recuperation of the cells of neurones, especially of those which are implicated in psychic processes, corresponds to the period of sleep of the individual. During every moment of the waking state the psychic apparatus is shaken by the stimuli to which it normally responds. Sensations, both common and special, are continually pouring in upon it, the ratiocinative processes now hold sway, and again the mind is occupied in the promulgation of volitional mandates, so that at the end of fourteen to eighteen hours of this incessant mental turmoil the cells of the psychic neurones are so far exhausted that they no longer readily respond to the stimuli of the environment. It is with difficulty that the processes are now made to extend and close up the gap between related neurones. Stimuli which ordinarily awaken the psychic apparatus into activity now fail to find their way into its precincts. The processes of the psychic neurones fall so far asunder that ordinary stimuli cannot cause them to meet in functional relation. The recuperative processes in the neurone then begin. Constructive metabolism takes up the process of removing the worn-out particles of the cell and of replacing them with new material. While this process is going on the neurone is absolutely dead to the outside world; its processes are so far retracted from others of its kind that outside stimuli cannot find their way to it.

The individual is now said to be asleep. His auditory centers no longer respond to sonorous waves; his common sensory neurones are no longer capable of transmitting stimuli to the center, and, save a few isolated areas of psychic neurones which keep up a feeble flow of thought known as dreams, the whole nervous system is in a state of functionless abeyance. This state prevails until such a time as the nerve-cell has been restored to its wonted activity, when its processes gradually become again extended, the ordinary stimuli of the environment now cause the processes to come into functional approximation with each other and the sleeper awakens. He now arises from his couch fresh and buoyant; problems which to him were insoluble the previous evening now clear up with astonishing lucidity; conclusions which appeared rational when he went to bed are now seen to be monstrous vagaries. He is now thinking with a refreshed and invigorated brain; his thoughts flow freely without any apparent effort and instead of the pessimistic views of the evening before he now sees the world in all its roseate aspects.

If the theory herein expounded is correct, and there is evidence upon every side to prove that such is the case, then sleep, instead of being the result of an outside influence exerted upon the brain as a whole, is due to metabolic changes which take place in the body of the nerve-cell as the result of normal fatigue.[1]

CLINICAL MEMORANDUM.

AN ATTACK OF URTICARIA OCCURRING IN THE TROPICS SIMULATING ANGIO-NEUROTIC EDEMA.

By JACOB S. GREEN, M.D.,
OF CENTRAL AMERICA.

Mr. D. came to me for treatment for what he called "prickly-heat." He complained of an intense itching and desire to scratch his entire body. This attack he said had suddenly come on the day he consulted me. The patient was a well-developed man, twenty-three years of age, plethoric, and had been taking very little exercise, whereas formerly he had exercised a great deal. Upon examination I found his face, body, and limbs covered with wheals of irregular shapes and various sizes, the largest being as large as a ten-cent piece. His temperature was 38° C. (100.4° F.) and there was a slight gastrointestinal disorder. He informed me that for a few days previous he had been indulging in claret wine with his meals, which was contrary to his usual custom at the table in the tropics. I advised a farinaceous diet and instructed my patient to take Epsom salts for a few days before breakfasting and to bathe his body with bay-rum. The next morning he returned to me with an increase of symptoms. I found the genitalia edematous, without pain on pressure, and the itching was more intense than on the day previous. I advised bathing the body with spirits of camphor. In the evening I was called to see him and found him in bed with his face swollen and particularly the eyelids and lips. He could hardly open the former and the latter he said felt very thick. The next morning all traces of the swelling of the genitalia and face had entirely disappeared, but the urticaria was still troublesome, it being relieved whenever he used the spirits of camphor. His hands were then very much inflamed and burned and itched greatly. His feet were in a like condition. I inquired into his family history regarding angio-neurotic edema but found it negative. I kept him on a light unstimulating diet and purged him freely. The next day he was much improved and had but a few wheals on his body. On the fifth day my patient was better. During no time was his temperature above 38.5° C. (100.5° F.), and the itching was always worse at night, in fact being so bad as to interfere greatly with his sleeping. The climate at that time of the year was very warm and the atmosphere very humid and oppressive. These conditions combined with a full-blooded temperament of the patient, excited to a higher pitch by alcohol, a meat diet, and a lack of exercise no doubt in this case produced the vasomotor disturbance.

[1] Those on the extremeties had entirely disappeared. The genitals were free and did not longer require any lotion although there was slight irritation. The eruption on the body which diminished hourly in extent continued to be somewhat irritable.

MEDICAL PROGRESS.

Amylen Hydrate in Diabetes Insipidus.—W. Niessen (*Therap. Monatshft.*, August, 1900) relates the case of a patient suffering from polyuria who was given amylen hydrate for insomnia with the unexpected result that the symptoms of his disease at once retrogressed. Following an extensive trial, the author concludes that small doses in many cases bring about a temporary improvement in the polyuria and polydipsia and, in a few, a permanent cure, thus making this drug, among the many others, worthy of consideration. The only drawbacks are the disagreeable taste and the insolubility of amylen hydrate which can be obviated by ordering it in capsules, to be followed by a glass of beer or wine.

Secondary Hemorrhage Following Use of Suprarenal.—The gratifying results which have attended the use of the suprarenal extract in intranasal surgery have made the introduction of this drug most rapid and its use, undoubtedly, a permanent one. After considerable experience, however, it has been found by many specialists that there is an important danger to be avoided in the matter of a secondary hemorrhage. F. E. Hopkins (*N. Y. Med. Jour.*, August 25, 1900) cites several cases in which he has had serious results from two to six hours after the use of this drug in nasal operations and also gives reports from many other authorities who have had similar experiences. Although the simple spraying of the nose with a suprarenal solution in cases of acute rhinitis has sometimes been followed by a secondary congestion even worse than the primary condition, this is a rare exception and the author believes that the serious secondary hemorrhages occur in those cases in which cocaine and the suprarenal extract have both been used. It would seem that the powerful stimulation to contraction of the swollen mucous membrane, induced by the suprarenal extract, while equal to retaining a grip on the dilated vessels for a time, is unable to prevent indefinitely the paralytic stage following the use of cocaine. He suggests therefore that the nasal fossæ should be carefully packed after each operation and, to be safe, an astringent should be employed.

Treatment of Diabetes.—An anonymous original article appears in the *Practitioner* (August,

1900) upon the methods of treatment of diabetes mellitus pursued by many of the leading authorities at the present time. In Von Noorden's clinic each patient is put upon a standard diet to determine what is the most appropriate dietetic treatment for each case. They are divided into three classes, one in which the sugar in the urine entirely disappears, a second in which it is lessened, and a third in which the quantity of sugar excreted is still great. The first class is then allowed more carbohydrates until the point of tolerance is reached, while the last two are put upon a gradually more restricted diet until the glycosuria disappears or their nutrition prohibits a further reduction of carbohydrates. In seven cases bicarbonate of sodium is given in large doses to prevent hyperacidity of the blood. The power of assimilation of carbohydrates is increased by periods of abstinence and patients are, therefore, much restricted in diet for a few days at regular intervals. Dieulafoy believes that in severe cases the kidneys should be flushed out by drinking large quantities of liquids and he does not object to the use of milk. He gives antipyrin morning and night and sodium bicarbonate daily. Very different views are expressed in regard to the advisability of using certain foods, which contain small amounts of carbohydrates. Dr. Hale-White believes that levulose can better be utilized than dextrose and he sometimes uses inulin, a starch corresponding to levulose. Grube notes that the use of phosphate and carbonate of lime increases the weight of the patient and makes them feel better, but has no effect upon the excretion of sugar. The hepatic extract has been found of slight value by Gilbert in some cases of liver origin. It is generally believed now that antipyrin diminishes the amount of sugar, but it should be used only in the very severe cases and only for a short time. Boracic acid has been found of use in a few cases and the prescription used was:

℞	Acid Borici	gr. xx
	Glycerini	ʒi
	Liq. Arsenici Hydrochlor.	♏ v
	Liq. Strych. Hydrochlor.	♏ x
	Aq. ad.	ʒi.

The thyroid extract and pancreas have proven useless. Several cases of diabetic coma have been successfully treated by the use of intravenous injections of normal saline solution. About 900 to 1200 cc. are generally used and repeated for several days if necessary. In England a seven-per-cent. solution of sodium chloride is used and four ounces in twenty-four hours have been known to be successful. If the patient is not in full coma, subcutaneous injection is usually better. Dr. Hale-White believes the rationale of this treatment to be that the toxin or poison is diluted by the saline injection.

Uterine Adnexa in Fibromata.—Greio (*Archivio Italiano di Ginecologia*, No. 2, 1900) draws the following conclusion on this subject: (1) In fibroma of the uterus, the tubes and ovaries are always altered, even though it may be but microscopically; there is always a hyperplasia of the muscular fibers and of the mucosa; sometimes only the mucosa is involved; this hyperplasia is of the same nature as the hyperplasia of the uterine mucosa. (2) From these alterations are often due the catarrhal and inflammatory processes in the tubes and ovaries. (3) There may also be an atresia of the tubes due to the tumefaction of the mucosa, or a diffuse adhesive inflammation; cysts are often found, associated with uterine fibromata, due to changes in the Wolffian bodies, or to a dilatation of the lymphatics. (4) Ovarian alterations, macroscopically, consist of a slight enlargement, with the presence of small cysts, which may or may not contain pus. The histological alterations in the ovaries consist of dilatation and obliteration of the blood-vessels with a hyaline degeneration of their walls and a proliferation of connective tissue stroma; these alterations produce a diminution of the primordial follicles, and a miscroscopic degeneration and atresia of the vesicles of Graaf, with the formation of fibrous bodies. (5) Uterine fibromata influence the adnexa mechanically by interference with the blood-supply, due either to direct pressure or indirectly by torsion, as in pedunculated tumors, causing a stasis of blood in the uterine adnexa; this stasis may extend to all the contents of the pelvis, causing a concomitant endometritis or a chronic inflammation of the peritoneal cavity. (6) It is well to remember that ectopic gestation may occur in uterine fibroid conditions and must be differentiated from the real alterations in the adnexa.

Thyrotomy.—F. Semon (*Lancet*, August 11, 1900) says that the laryngoscope and internal laryngeal surgery have for many years supplanted external thyrotomy, especially in two of the latter's indications, namely, the removal of foreign bodies and the ablation of benign growths. In fact authorities like Professor Paul Bruns prefer internal laryngeal means even for malignant neoplasms. Improved technic both of the operation itself and of the after-treatment has done away with most of the objections which previously had to be admitted as in force. All indications for an operation are facultative when another and compulsory where no other method may be substituted. Under these two categories the indications of thyrotomy may be regarded (1) foreign bodies in the larynx; (2) injuries to the larynx; (3) laryngocele; (4) stenosis of the larynx; (5) acute laryngeal perichondritis; (6) laryngeal tuberculosis, including lupus; (7) scleroma of the larynx; (8) benign; (9) malign new growths of the larynx. Foreign bodies should always be removed when possible by the natural path. When this is not practicable we have at disposal tracheotomy, dislodgement through the wound or from above or through a thyrotomy. Each case is a law to itself, the kind, site, impaction of the body and the result-

ing symptoms determine what shall be done. Injuries of larynx may be repaired, fragments ablated or apposed and maintained in apposition by a thyrotomy. Laryngoceles or air-cysts of the larynx are very rare and still more seldom do they cause dangerous symptoms, but in such circumstances would be a reason for thyrotomy. Laryngeal stenosis due to tuberculous or syphilitic ulcers or scalds and burns of the mucosa, fractures, adhesions inflammatory or congenital, malformations, etc., will readily be managed by a thyrotomy. Certain cases may be handled by dilation with O'Dwyer's or Schrötter's tubes or by intralaryngeal approach, but in the main freedom of access is gained by the open method. Acute laryngeal perichondritis, especially when abscess and necrosis ensue, is readily treated thus because evacuation of pus, removal of necrotic tissue, drainage and after-treatment are so readily carried out. Tuberculosis of the larynx, including lupus, yields good results to thyrotomy when the general strength of the patient is good, very poor results when the systemic disease has gone far. Hence the latter condition is an absolute contraindication of it. Another difficulty is the frequency with which the wound itself becomes a tuberculous sinus and requires much after-treatment to cure. Scleroma of the larynx is very rare. Thyrotomy followed by systematic dilatation should relieve or cure. Benign and malign neoplasms are very likely the greatest field for this operation, because it gives wide exposure and free field.

Koplik's Spots and Measles.—Koplik's spots consist of irregular spots of a bright red color, with a minute bluish-white speck in the center of each, which appear on the buccal and labial mucous membrane during the invasion of measles from twenty-four hours to five days before the cutaneous outbreak and fade away as the skin eruption reaches its height. These spots vary in diameter from 0.2 to 1 mm. and are found to consist of bacteria and epithelial scales. They cannot be removed by rubbing with the finger. At first there may be only from one to six of these spots, but they may increase in number until they cover the whole inner surface of the cheeks and lips and coalesce so that the whole buccal mucous membrane becomes of a uniform red color studded with myriads of these bluish-white specks. The combination of a bluish-white speck in a rose-red spot is absolutely pathognomonic of the invasion of measles. Jose L. Hirsh (*Phila. Med. Jour.*, August 25, 1900) says that the diagnostic value of this sign does not seem to be generally appreciated. He thinks these spots on the buccal mucous membrane are alone significant and pathognomonic of beginning measles, and says that, although he has never been able to see them with an artificial light, they are easily visible in strong daylight. He says that this characteristic eruption can be easily distinguished from all other eruptions occurring in the mouth by the peculiar bluish-white speck which is in the center of each red spot. The absence of Koplik's spots precludes the diagnosis of measles, while their presence as surely establishes the invasion of measles. The writer cites some interesting statistics by a number of investigators. He has found these spots present in every one of between forty and fifty cases of measles, but never in cases of any other disease. He reports in detail five cases which showed these spots and had measles; two cases in which the absence of Koplik's spots caused another diagnosis to be made which was afterward confirmed; one case of measles, in a colored boy, in which the presence of Koplik's spots was necessary for a diagnosis as the cutaneous eruption was atypical and hard to see; and a case in which the spots were present during the invasion of a second attack of measles. By this sign measles may be diagnosticated from one to five days before the cutaneous outbreak. Hirsh presents the following conclusions: (1) An eruption, limited to the buccal and labial mucous membrane and characterized by the presence of irregular red spots with a bluish-white center, is always present in beginning measles; (2) these spots are present from twelve hours to five days before the cutaneous outbreak; (3) the number of these spots bears no relation to the severity of the attack; (4) these spots will be found in no other condition of health or disease.

Carbolic Acid and Mastoiditis.—W. C. Phillips (*Med. Rec.*, August 25, 1900) says that pure carbolic acid is without peer in the treatment of suppurative conditions about the ear and its accessory channels. It may be applied with a cotton swab or by an atomizer, allowed to remain *in situ* thirty to sixty seconds and neutralized by alcohol. Under its use unhealthy granulations become normal, discharge ceases and often secondary operations are avoided.

Ichthargon.—This is a combination of ichthyol with a silver salt, which, according to L. Leistikow (*Monatshft. f. prakt. Dermatolog.*, August 15, 1900), is especially to be recommended in acute anterior gonorrhea since it possesses to a marked degree the antiphlogistic and antiseptic properties of its component parts and at the same time is no more irritating than the ichthyol alone. It can be had in the form of a dark brown, odorless powder, readily soluble in water and containing 30 per cent. and 15 per cent. sulphur in combination. In drawing conclusions from the numerous cases the author cites in full, it appears that in many cases ichthargon acts as an abortive; at all events a cure is reached in a remarkably short period and the disease is not prone to be complicated by other inflammations. It is not necessary to resort to the expectant plan of treatment at first, but injections, varying from 0.02-0.2 per cent. in strength, may be employed with success from the very onset. The author earnestly solicits a more extensive use of the drug by the profession.

Tumor Albus.—The common synonyms of this term, says F. E. Peckham (*Med. Rec.*, August 25, 1900) are white swelling and tuberculosis of the knee-joint. The important early symptoms are heat, swelling, tenderness, distention, bogginess in the absence of fluid, depression of the patella by swelling of tissues about it. When the joint is opened this is found to be due to the accumulation of a peculiar gelatinous material within the cavity whether fluid is present or not. The inner condyle of the femur is apt to be the more involved. This produces a condition simulating knock-knee, if at all marked. Lameness next appears and may at first be intermittent. With increasing irritability the flexor muscles become slowly contracted and then flexion and subluxation ensue and are characteristic deformities. Muscular atrophy distal and proximal to the joint becomes manifest. Locally temperature is appreciably elevated. By stimulation of the epiphyseal growth sometimes actual lengthening occurs for a time. Pain appears early and becomes greater and greater if treatment is delayed. Then appear anxiety, loss of flesh and strength, fever, anorexia, etc. This important disease is to be differentiated from synovitis, rheumatism, rheumatoid arthritis and hysterical joints. Synovitis, especially if the body resistance is lowered, is difficult to eliminate, but the patella here floats on fluid, is not surrounded nor covered by a boggy mass and hence strikes the femur with a distinct click. Motion is not much interfered with. Atrophy is absent. Acute rheumatism has a sudden onset with fever and more than one joint may be affected. Chronic rheumatism is clinically sometimes impossible to differentiate. In rheumatoid arthritis the bony spindle-form joint enlargement and the distinct bony crepitus due to erosion of the joint surfaces and the presence of the disease in several joints make up its salient features. Hysterical joints may be recognized only after watching the case. The treatment comprises conservative fixation, rest and protection, with tonics and fresh air, radical opening and scraping of the joint, excision in bad cases, amputation as a preservative of life.

Etiology of Anosmia.—The central course of the olfactory fibers is as yet too imperfectly known to allow one to localize the tracts and centers which control smell, hence the factors which cause disturbance of this sense cannot always be determined. A. Onodi (*Klin. therap. Woch.*, August 12, 1900) finds it convenient to divide anosmia into essential or true, mechanical or respiratory and functional. The first mentioned may be centric or peripheral and among its causes may be mentioned influenza, syphilitic processes in the nose, polypi, chronic ethmoiditis and atrophy of the mucosa for the peripheral types. Brain tumors located in the interior fossa, cerebral abscess, hydrops of the ventricles, syringomyelia, progressive paresis, cerebral tabes and senile atrophy, for the centric, are most common. The second group includes all those forms in which there are mechanical impediments to respiration; such as atresia of the choanæ, deviations of the septum, etc. Functional anosmia generally depends on hysteria, but may occur reflexly during menstruation, after removal of the Gasserian ganglion, cauterization of the inferior turbinated or ovariotomy. Parosmia and kakosmia may precede any form of anosmia.

Roentgen-Ray Errors.—In treating of the use and interpretation of the skiagraph, Carl Beck (*Med. Rec.*, August 25, 1900) says that its advent into the hands of surgeons has revolutionized at least the diagnosis of fractures. After an experience of nearly three thousand cases he has found dermatitis of rare occurrence and always due to some trophic disturbance in the individual. He has had two instances of circumscribed depilation, due to frequently repeated necessary exposures. The hair returned within a month. To interpret a skiagraph properly appreciation must be at hand of the facts that one is dealing with photographs of shadows and that each tissue casts one. Muscles and tendons have a large share in the difficulties of interpretation. The carpus, as an example, is especially apt to produce errors, the tuberosities of the trapezium, scaphoid hamulus ossis hamati, os pisiforme, eminentia carpi volaris and ulnaris double the thickness of the carpus, cause dark shadows and might lead to error. The foot is easily skiagraphed in the direction from the dorsum to the planta pedis as far back as the upper third of the metatarsus. Farther back the cuneiform and scaphoid and other tarsal bones bring in difficulties, so that lateral views must be taken to substantiate the other. Thus the astragalus, calcaneum, cuboid, scaphoid, fifth and fourth metatarsal bones are brought out clearly. Knowledge of the normal sesamoids is also essential in order not to be drawn into error by their presence. The os trigonum tarsi has also been the source of much difficulty and one must be prepared to meet it rather frequently. The practitioner must also be aware of the various other common anatomical abnormalities. A normal semitendinosus sesamoid bone occurs in 8 per cent. of all cases. The significance of the skiagraph in estimating the amount of functional disability is not always conclusive. Bony deformity may be present without marked or in fact any loss of function, in fact where function is perfect the union may be skiagraphically imperfect. On the other hand, marked depreciation of the use of a limb may occur by injury of the soft parts, whereas the skiagraph may be negative. Joints offer the next obstacle. The more complicated the joint the greater the difficulty and the more emphatic the indication for examining both sides. Old fractures can often not be diagnosticated, unless displacement and callus exist. Intra-articular fractures are especially difficult because the callus may hide the line and the joint complexities add still more to the problem.

Here again the normal opposite side should be skiagraphed and often the comparison of these with a skeleton will be essential to clear knowledge. In children and adolescents the years at which the epiphyo-diaphyseal bony union occurs must be known, together with the ossified bones at birth and the relation such diseases as rickets bear to ossifications and union. Foreign bodies require a skiagraph for each axis. A needle seen end on would appear as a point and be overlooked, side on as a narrow black shadow one inch or more long. In order to be of legal value the skiagraph must have records with it of the source of the current (battery, static machine or street), of the length of the spark of the induction coil, of the intensity of the tube, of the distance of the platinum disc of the tube from the plate, of the position of the object, of the kind of plates and of the time of exposure, together with full clinical and anatomical data.

Coating of the Tongue.—Although the modern physician attaches much less importance to the condition of the tongue than was the case formerly, and although a uniformity in the extent and character of the furring is hardly to be expected even in disease of the gastrointestinal tract, as an aid to diagnosis the tongue should not be overlooked or its appearance regarded as unimportant. J. Müller (*Münch. med. Woch.*, August 14, 1900) finds that but few healthy persons can boast of a perfectly clean tongue; in the majority a thick or thin deposit is found in the center and along the posterior portion, leaving the edges free. This more or less normal condition is not dependent, however, so much on a true coating but is caused by enlargement of the filiform papillæ whose surfaces are in constant desquamation. Between these papillæ mucus, epithelium, leucocytes and remnants of food, together with an extensive bacterial flora, are found. This forms the true coating which can readily be scraped off with a knife, leaving, however, in most cases a much more extensive fur consisting of papillæ, which cannot be removed. In disease the furring is most marked if the attack be acute, whether or not it be located in the alimentary canal, while in chronic digestive troubles the tongue is often no more coated than in health. An examination of the scrapings showed that they did not differ from those in health except that in gastric cancer and in pulmonary tuberculosis many leucocytes were found. The author believes that several factors produce the furring of disease. Owing to the diminished amount of food the patient takes the tongue is less frequently cleaned by the mechanical act of chewing. Also the mouth is often the seat of a desquamative catarrh which permits of an increase of the epithelial elements of the fur. To decide whether the condition of the tongue is normal or pathological it is best to scrape off part of the fur; in the latter case, much more can be detached than in the former. As far as therapy is concerned, the removal of a healthy fur is not to be practised since it will dispose to more marked deposition. In disease, however, it is best to clean the tongue with a dense and soft toothbrush which can reach the posterior portions.

Foreign Body in the Bladder.—J. H. Morgan (*Lancet*, August 11, 1900) describes a case of foreign body in the bladder consisting of a clinical thermometer. Had an X-ray photograph been resorted to the nature of the nucleus of the stone would have been found for both glass and mercury are very opaque to the rays. Foreign bodies are found oftener in the female than in the male bladder, probably on account of the shorter urethra and of the more frequent occurrence of hysteria. This patient had lumbar and hypogastric pain, alkaline, low specific gravity, purulent urine, slight rise of temperature at night, dysuria and frequency of urination. The treatment was irrigation with boric acid twice daily and boric acid and ammonium benzoate internally. Later lithotripsy when the nature of the stone was revealed. Recovery was complete.

On Epistaxis.—W. Lamb (*Birmingham Med. Rev.*, August, 1900) gives an excellent account of the arterial supply of the nose and dwells on the difficulties of checking hemorrhage owing to the vascularity of the cavity which is dark, full of recesses, difficult of illumination and freely open at both ends, while the lining membrane, especially that covering the lower turbinated body, resembles the erectile tissue of the corpora cavernosa. Constitutional diseases, with a tendency to hemorrhage or conditions of increased blood-pressure, may result in epistaxis, but most common are erosions of the mucous membrane of the septum, especially at its lower and anterior part, about half an inch from the entrance of the nostril. The reason for this is that this spot is most exposed to injury by the finger-nail when it is used to pick off the adherent crusts which form in the dry varieties of rhinitis. Bleeding from the upper and anterior regions is much less common and is generally associated with congestive head symptoms. In the treatment of epistaxis, the first point to decide is whether any treatment is needed. Patients in whom the epistaxis has relieved head symptoms should be allowed to bleed moderately. In other cases plugging the lower meatus and thus compressing the whole length of the inferior turbinated body is best. Plugging the posterior nares with Bellocq's sound is an operation which should be reserved for cases bleeding from the nasopharynx. Erosions of the mucous membrane may be touched with the galvanocautery at a very dull red heat. A chemical caustic which the author has effectually used to check bleeding is common precipitated sulphur. When applied to raw surfaces it forms sulphurous acid which exerts its powerful effects efficiently upon the tissues without causing any pain. Hot water, peroxide of hydrogen, and suprarenal ex-

tract may be tried; calcium chloride should be given internally in hemophilia, and turpentine in purpura.

The Pathology of Diabetes.—Although the true cause or causes of diabetes are very uncertain and indefinite, the malady is one in which experimental physiology is of great assistance in determining the nature of the condition, for artificial diabetes can be caused in a variety of ways. The recent experimental work is reviewed by J. R. Bradford in the *Practitioner* (August, 1900). The fundamental fact in the pathology of the disease is that the blood contains an excess of sugar which may theoretically be due to a number of causes: (1) Too great an ingestion of sugar so that the liver is unable to arrest it, either on account of the amount taken in or because of a functional derangement of the liver. (2) The excessive formation of sugar. It is believed by some that the liver is a sugar-forming organ as well as sugar-stopping, and that it can, perhaps pathologically, make sugar out of proteids and possibly fats. Thus this form of diabetes could not be entirely controlled by the amount of carbohydrates ingested. (3) Disturbances in the functions of the pancreas. Some contend that there is an internal secretion by the pancreas which assists in the oxidation of the sugar by the tissues. In favor of the first view are the many cases which have a glycosuria without many symptoms and which clears up when the ingestion of carbohydrates is controlled. In such patients it is possible that the maltose is converted into dextrose too rapidly for absorption by the liver or the liver-cells may be so deranged that they fail to arrest a normal quantity of dextrose and convert it into glycogen. In regard to the second explanation—that the glycosuria is due to hepatic trouble—it is abundantly proved that it may occur under nervous influences, inasmuch as a number of experimental lesions of the nervous system are capable of producing glycosuria. The passage of arterial blood through the portal vein has the same effect. Recently lesions of the pancreas have been proven to be efficient causes of glycosuria. It may be produced by extirpation of the whole gland or ligature of the pancreatic veins and it is now well known that the gland has an internal secretion the absence of which is followed by glycosuria. Lepine explains the phenomenon by saying that the pancreas produces a glycolytic ferment which is essential to the metabolism of sugar and prevents its accumulation in the blood. The pancreas is also supposed to secrete some important element into the lymphatic system for ligature of the thoracic duct also produces glycosuria, but it has been found by Gaglio that excision of the pancreas does not cause diabetes after ligature of the thoracic duct. A fairly satisfactory explanation of pancreatic diabetes is that the pancreas secretes into the lymph-stream an internal secretion capable of neutralizing a toxic body which is continually being absorbed by the intestine and which can in itself produce a glycosuria. It is thus necessary to suppose that the intestinal toxic substance is absorbed both by the portal and lymphatic systems.

Malignant Disease of the Stomach and Pylorus.—W. J. Mayo (*Annals of Surgery*, August, 1900) says that age has a more important bearing on carcinoma of the stomach than on the same disease in the lower portion of the gastro-intestinal tract; in the former locality it is peculiarly a disease of middle and later life; under thirty it is most rare. The progress of the disease varies greatly and is materially affected by the age of the patient, the situation of the growth, and its histological structure. Death may follow in three months from the first symptoms, or it may be delayed to two and one-half years—the majority die within the year. A suspicion of gastric cancer should cause the physician to send the patient to a surgeon for exploratory incision to complete the chemical examinations already supposedly made in a suspicious case; the same principles should govern here as in probable malignant disease of the breast or uterus. In a general way it can be said that the early medical diagnosis of cancer of the stomach does not depend on any specific sign or symptom, but rather on a collection of facts, each one of which, if taken alone, would have but little value; moreover, most of the symptoms are not developed to a characteristic extent until late. If a person of middle or advanced life of previous good digestive power begins to complain of pain in the region of the stomach, difficult digestion and loss of appetite, with a progressive loss of flesh and strength, with more or less vomiting, cancer of the stomach is to be suspected; unfortunately if all these symptoms are present, the probability is, that it is too late for a radical operation to be of any lasting avail. The curability of cancer of the stomach depends on the histological structure of the neoplasm; its location; extension to neighboring structures; lymphatic infection; and the general condition of the patient. Prompt and early radical surgical treatment affords the only check to the ravages of this dread disease.

Disease of Upper Air-Passages and Diphtheria Bacillus.—Evidence that a single organism may under certain circumstances be capable of producing widely differing disease states is rapidly accumulating and a series of five cases reported by Neisser and Kahnert (*Deutsche med. Woch.*, August 16, 1900) seems to confirm this already suspected property in the diphtheria bacillus. The patients in question suffered from a well-marked degree of atrophy of the mucosa accompanied by hypertrophy of the follicles and oversecretion of thick, stringy mucus which exhibited a tendency to desiccation and the formation of crusts. The lining membrane of the nasopharynx, pharynx and upper larynx, was invaded in all the cases which also were characterized by resistance to

treatment and spontaneous remissions in summer. Subjectively dryness of the throat, pain and hoarseness were complained of. On bacteriological examination the secretion was found to be rich in organisms which apparently were true diphtheria bacilli and an antitoxin reaction could be obtained from the blood.

Gastric Carcinoma Simulating Esophageal Stenosis.—In this case, described by R. Schütz (*Deutsche med. Woch.*, August 16, 1900) a dilatation of the lower portion of the esophagus served to supplement the diminished receptive capacity of the stomach which was greatly contracted owing to a malignant growth starting at the pylorus and invading nearly the whole wall. The anamnesis was very atypical inasmuch as there had never been vomiting or any symptoms pointing to a secondary dilation and a gradually increasing dysphagia first for solids and later for fluids seemed to locate the disease in the esophagus. On autopsy it was found that although no tumor had been palpable during life the stomach had been transformed into a rigid thick-walled vertical tube while there was evidence of great relaxation of the lower esophageal wall. The peculiar position of the stomach produced through the contraction of peritoneal adhesions must be regarded as the crucial factor in the clinical picture, for owing to its vertical direction it became simply a continuation of the esophagus and although a high degree of motor insufficiency existed no dilation was produced. The seeming esophageal stenosis which had, however, never presented any difficulties to the passage of either hard or soft bougies resolved itself simply into atony of its muscular coats.

Chills in Typhoid Fever.—In southern latitudes the exhibition of chills in typhoid fever is usually considered to be due to a combination of malaria with the enteric fever. This double infection, writes W. W. Ford (*Montreal Med. Jour.*, July, 1900), may occur, but often the chills are due to septicemia either from absorption of toxic products or from the growth and development of the typhoid bacillus in the blood. A case of this kind occurred at the Johns Hopkins Hospital, showing marked Widal reaction, typhoid bacilli in the urine and in the blood, and typhoid ulcers at autopsy. The rigors were always very severe, the rise and fall of temperature abrupt, and accompanied by shaking chills and sweating. Such pronounced chills are seen only in malaria and septicemia and the former was ruled out by the constant failure to find the parasite in the blood and the lack of any lesions at autopsy associated with malaria. Chills in typhoid are usually ascribed to the more serious complications such as cerebral thrombosis, hemorrhages, or intestinal perforation. Yet none of these were present, and the finding of the bacillus in the blood corroborated the diagnosis of typhoid septicemia.

Adiposis Dolorosa.—V. Giudiceandrea (*Revista di Pat. nerv. e ment.*, July, 1900) records the case of a woman, aged forty-four, whose hereditary and personal history prior to the beginning of the symptoms was negative; eight years ago she began to have sharp shooting pains in the sacral region extending down into the left thigh; the pains at times were so severe as to require the use of morphine; these pains were paroxysmal for two years, when she noticed a falling out of her hair; about this time the pains again became acute and continued, involving now the right lower extremity as well, until three years ago the pains had involved most of the body; *i. e.*, the abdomen, the breast, the shoulder-blades, and even the hands. Contemporaneously an increased deposit of flesh was noted, first in the left buttock and thigh, and then in the right thigh; the pains always grew worse prior to a noted deposit of fat; finally the abdomen, the breasts, the shoulders and upper extremities were the seat of fatty deposits, until locomotion became painful because of these deposits and the concomitant pains. Examination showed her skin and mucous membranes to be pale; the subcutaneous tissues were found to be the seat of enormous fatty deposits somewhat irregularly situated. The thyroid gland was normal in size; there were no ataxic symptoms; reflexes were normal; tactile sensibility was marked, indeed being most painful over the areas of fleshy deposit, while heat sensibility was diminished; electric examination was normal, as was her psychic state; the heart was hypertrophied; the liver and spleen were slightly enlarged. Under continued thyroid gland administration the patient improved considerably, both as to her weight and the hyperesthesia previously existing. The author's conclusions are that adiposis dolorosa usually appears in women between the age of thirty-five and sixty years; syphilis and alcoholism are supposed to be predominating causes; traumatism may be a cause also; only seventeen cases have been recorded. The fatty deposit manifests itself in a nodular, a diffuse, or a combined nodular and diffuse form; the pains are either spontaneous or due to pressure; the pains may precede or be coincident with the fleshy deposits; pressure pains are most severe where the fat deposit is most abundant; the disturbances of sensibility are many as are those of motility, the latter being due to mechanical interference of the fatty tissue; muscular atrophy may occur from disuse. The heart, spleen and liver are usually enlarged; the temperature is generally normal; the pulse is frequent; the blood is likely to be deficient in red blood-cells; the course of the disease is usually progressively fatal, although it may be altered by organotherapy; the diagnosis is fairly easy but this disease must not be confused with myxedema, acromegaly, elephantiasis or obesity. The treatment is largely empirical, electricity, massage, tonics, baths, and thyroid extract, offering the best results thus far obtainable.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

THE PLAGUE.

THE appearance of the plague in Glasgow adds another and very important port to the number already on the alarm-list of quarantine officials. The inconvenience and delay to which passengers of the "City of Rome" were subjected on its arrival after the news of the plague were trifling things in comparison with the importance of making the most rigid examination of every passenger and member of the crew of ships sailing from any infected port.

This is no summer scare to fill vacant spaces in newspapers. It is a very serious danger, but the fact that the hue and cry last November, when two cases came with the coffee cargo from Santos, soon died away, and the fact that the scare this summer will doubtless amount to nothing, must not delude the public into thinking that the health officers are "crying wolf." The scare will come again, year after year, with the deadly persistence of the *bacillus pestis* and the greatest danger is that familiarity will breed contempt, and that at some small, not too sanitary port, where the sentry duty weakens, through constant, unrecognized alarms, the plague will touch our shores and become acclimatized.

The position and commerce of the North American continent are such that every additional infected port in any part of the world threatens our shores.

Five years ago this present outburst of the plague started in India; to-day it has spread to Asia and Africa until it has reached the limits of their coasts. Hong Kong and Japan threaten us on our Western and most susceptible shore; Alexandria, the most frequented of the African plague ports, with Oporto and Lisbon and other ports in Spain, threaten our Eastern coast, especially through their commerce with South America where the plague has appeared in Rio Janeiro, Asuncion, Santos, and other insanitary cities.

At the present time the problem is not so much, what shall be done during the temporary fright this summer? but what provision shall be made in every seaport of the United States during the next ten years to guard against the pertinacity of the plague?

The plague that started in the sixth century in Egypt and which caused 10,000 deaths in a single day in Constantinople took thirty years to overrun Gaul and Spain, and the second great plague that started in China in 1334 took thirteen years to travel to Europe; but when it finally did arrive 25,000,000 died. The plague that came two years ago to Vienna, done up in test-tubes for inoculating animals, and that caused the death of the bacteriologist who experimented with it as well as of the attendant who nursed him, was immediately stamped out to the great relief of the excited Viennese; but it was an accidental and not an acclimatized outbreak. Even in Glasgow the few cases reported need not worry the British Isles just yet, for the bacillus cannot have become accustomed to the new climate and conditions. The plague will disappear from Glasgow just as it disappeared from San Francisco, but that must not cajole a too-easily-frightened people into a too-easily-won relief. The plague is a thing with the persistence of half a century in its vitality and the Government should recognize this and take precautionary measures, which, however expensive and irritating and inconvenient they may be, cannot compare with the terror and horror of the "Black Death."

These measures should be, first, the establishing of strict and efficient quarantine for a term of years at every small port, especially on our Southern and Western coasts, in Cuba and the Philippines, as well as a cooperative quarantine on the boundary of Canada, where it is trusted

the smaller ports will also be strictly watched. Second, the introduction of sanitary and hygienic improvements in crowded and unclean seaports, especially in the warmer climates. England is depending more largely on its cleanliness than on elaborate quarantine for immunity. Third, the study of how best to destroy rats, mice and fleas, both on land and sea, as these have been proved to be most pernicious carriers of the disease. Fourth, the enforcing of an absolute isolation of all cases coming from badly infected ports until the term of incubation has passed. It was a source of surprise that when the plague was raging in ports all about, Singapore remained immune, even though ships with 3000 to 4000 coolies were arriving from China; but the immunity was due not to disinfection of cargoes, which was little practised, but to the fact that all passengers were detained nine days before landing, thus giving the disease time to appear before they left the ship to scatter it broadcast. Lastly, we would recommend a careful study of the symptoms of the plague, especially of the hitherto rather overlooked preliminary symptoms of the respiratory tract, with a view to early diagnosis.

We cannot too heartily commend the active work done by the Marine Hospital Service in their studies of preventive inoculation for the plague and we confidently look forward to the time when this final means of protection shall be assured to us.

SUMMER INFANT FEEDING.

A great change has come over expert opinion during these last few years with reference to infant feeding in the warm weather. Medical men who recall the enthusiasm with which the sterilization and afterward the pasteurization of milk for infant feeding were taken up by the pediatrists at the beginning of the present decade can scarcely help being surprised at the position now generally assumed by specialists in children's diseases with regard to this important matter of infantile diet. The change, we are happy to say, is not the result of caprice nor the mere desire for novelty. It represents a distinct advance in the knowledge of infant dietetics although it seems to be only a return to methods of feeding which have been in general use for a long time before science invaded the field of child food preparation.

The change is due to two principles that now seem to have been definitely established. These are, first, that the mixture of a certain amount of some cereal with cow's milk for babies' food instead of being harmful is beneficial. Second, while sterilization or pasteurization of milk does destroy all living germs in it, neither process destroys the toxins that may have been elaborated by the germs during their period of vital activity. Some of these toxic substances are very virulent. Because of them or because of some change in the milk under the influence of heat, sterilized or pasteurized milk often becomes markedly indigestible. Certain infants seem to receive no nourishment from it. It has taken a good while to realize the truth of these principles. Their acceptance however promises to be of the greatest practical importance in the nutrition of infants.

With reference to the mixture of cereals with cow's milk for very young children there are authorities on the subject, like our own Professor Jacobi, who have always insisted on the benefit to be derived from them. When it seemed demonstrated that the infant secretes no starch-splitting ferment and can therefore make no use of starchy substances, these men on the strength of their clinical observations still recommended the use of a certain amount of cereals. If they had not a chemical significance at least they were of physical import in the child, digestive economy, for it was certain that their presence greatly aided the infant nutrition. If they were not absorbed at least they served the very advantageous purpose of mechanically breaking up the coagulum, which in cow's milk is prone to be dense. At the present time there are advanced on experimental and clinical grounds additional good reasons for the employment of cereals in infants' foods.

The diastasic ferments that aid in the digestion of starch have been proved to be present at a much earlier period in infantile life than has been claimed. Even the very young infant is able to avail itself of a certain amount of starchy material. An important although hitherto unsuspected action of carbohydrates when added to cow's milk is that they decrease nitrogenous elimination. When maltose was added to the cow's milk of a baby's dietary Keller found that the elimination of nitrogen was reduced to less than one half what it was before. The striking difference between mother's milk and cow's milk as far as regards infant nutrition seems to be that while most of the nitrogenous material

absorbed by the breastfed infant is retained—a percentage of retention as high as 80 per cent. has been noted—the bottlefed infant on a diet of cow's milk alone retains very little of the nitrogenous substances absorbed—in one case only a trifle more than 5 per cent. of the amount supplied. This rule applying to the retention of important albuminous material holds also for children who are not well. In them the nitrogenous waste when on an exclusive cow's milk diet is prone to be excessive, sometimes reaching 99 per cent. of the amount ingested. The addition of a carbohydrate to the food at once reduces this waste and leads to the retention of albumins in the system.

Professor Heubner, of the Children's Clinic at the University of Berlin, arrives at a similar conclusion as to the value of carbohydrates in infant's diet from a very different method of observation. Heubner studied the complete metabolism of the infant when placed in a glass chamber connected with a respiration apparatus. As the result of his experiments he emphasizes the importance of non-nitrogenous foods because they protect the albumins from useless decomposition. Infant growth requires the retention of considerable amounts of albuminous materials in the system, but these are not retained unless non-nitrogenous foodstuffs in certain quantities are being constantly given. It seems probable that fats are as important as the sugars in preventing useless decomposition of nitrogenous substances, but both must be given to insure the retention of the proper amount of albuminous material within the child's body.

These latest conclusions of experimental pediatry seem thoroughly rational. They agree much better with the traditions of infant feeding than did the seemingly more scientifically exact regulations of a few years ago. If applied with a due admixture of common sense they will undoubtedly prove of the greatest service during warm weather. We have now come to the realization that sterilization or pasteurization may render less harmful but cannot change the character of an originally contaminated milk. What is needed for successful infant feeding is the purest possible milk, kept on ice from the time it is gathered until its distribution, and not allowed to stand in the warm air of a house for hours before being used. This, mixed with the amount of cereal in the form of barley-water or something similar that has been found to agree with the particular child and with the amount of cream that seems advisable for the special milk, and the little patient will do much to ward off the dangers of an unsuitable diet during the warm weather.

CONCERNING LAMINECTOMY IN FRACTURE OF THE SPINE.

In spite of our progress in the past quarter of a century, we still continue to adhere with fruitless tenacity to enough antiquated and properly obsolete procedures in both medicine and surgery to arouse the suspicions that a certain amount of this progression is alarmingly crabwise.

It is certainly discouraging to think that since the operation of trepanning the vertebræ for fracture was attempted by Mr. Henry Cline, at St. Thomas' Hospital, in London in 1814, sufficient good has never come from it up to the present day to warrant the performance of it—or its modern counterpart laminectomy—except in certain cases whose number is dangerously near the vanishing point. Why, therefore, an operation so absolutely barren of results should continue to be perpetuated by generation after generation of surgeons surpasses understanding. Too often, we fear, it is undertaken on the flimsy ground that it offers the last chance. In regard to this plea we can only say that the surgeon who makes it must be woefully unmindful of his own previous experience as well as of the accumulated experience of the century, for certainly we can think of no operation in the entire category upon which we may count more surely to remove the last chance, than upon the one in question.

When we read some of the most modern writings upon the subject in which the advantages and disadvantages of laminectomy for spinal fractures are discussed with as much naïveté as if the author had embarked alone upon a tour of discovery and had penetrated to the heart of some hitherto undiscovered country, we shudder to think of how quickly even middle-aged medical writers pass into oblivion. Many years ago one of the shining lights among English essayists, William Hazlitt, complained bitterly of the neglect of the age for old writers and accused his contemporaries of an assumed and insincere admiration for these writers to whose names they always took care to refer with a proper show of reverence, while they carefully refrained from any actual acquaintance with their works.

Whether Hazlitt's criticism also applied to

the medical profession of the day we do not know, but it certainly does to ours, and it can hardly be gainsaid that a closer intimacy with the work of our medical great-grandfathers would exert a praiseworthy restraint upon our actions. The results of our ignorance of these ancient tomes are always amusing and not seldom redound but seantily to our credit. Witness the logomachy which waged two or three years ago between two of the best known French surgeons before the highest medical tribunal in France, for priority of claim to a procedure (the forcible reduction of vertebral gibbosities in Pott's disease) which, according to authentic records, Hippocrates adopted from a predecessor.

With regard to laminectomy for spinal fracture, a brief historical retrospect reveals some interesting facts. Away back in the second decade of the century it was the unfortunate rock upon which split such eminent authorities as Sir Charles Bell and Sir Astley Cooper; the one contending for, the other against, the operation with a bitterness of spirit sufficient to make the latter give vent to such epithets against his adversary as "blockhead" and "foolish person," while Mr. Bell gave the retort discourteous by accusing his calumniator of "gross ignorance and a wrong mode of teaching."

In those early days who was to decide when such giants fell out? From their time on, however, every observer of note has condemned the operation in the class of cases under consideration in unequivocal terms, and we need come no further forward in the century than 1845 to find in the Fothergillian Gold Medal Essay on the Curvatures and Diseases of the Spine by R. W. Bamfield, Esq., London, this condemnation expressed in terms as scientific, and for reasons as cogent, as any that can be advanced at the present hour.

That the next thirty-four years had done nothing to remove this surgical anathema is obvious from the following quotation from the work of the most eminent neurologist of his day in Germany, Leyden. (Klinik der Rückenmarks-Krankheiten, Vol. I., p. 347). He says: "Doch haben sich schliesslich die Chirurgen von dieser höchst undankbaren Operation abgewendet und sie ist, soviel mir bekannt, in den letzten Jahren nur von den kühnen and operationslustigen Amerikanern gemacht. (Still surgeons have finally abandoned this supremely thankless operation and—so far as I know—it is undertaken in recent years only by the enterprising and operatively-inclined Americans.") We have turned the expression "kühnen und operationslustigen" as mildly as possible; it is capable of an infinitely more ironical rendering. We cannot, however, refrain from emphasizing the distinction which the author makes, either consciously or unconsciously, between surgeons and Americans. The biting sarcasm of this utterance should have been sufficient in itself to thrust the operation at once into innocuous desuetude in this country. But it was not, and the "operationslustigen" have continued, with a persistency which baffles comprehension, to contribute grewsome data and new-old ideas concerning a surgical procedure which should have passed into the darkest oblivion many decades back.

He would indeed be a "foolish person" and "a blockhead" who would attempt to deny that enormous advances have been made both in surgery and in neurology since the days of Cooper and Bell, and even since Leyden's time, but equally unduly confident is he who thinks that such advances have brought us any nearer to the solution of the problem under consideration. Notwithstanding all this we feel sure that there are those who will continue to look forward with the utmost confidence and hope for brilliant results from laminectomy in spinal fractures. For the benefit of such we cannot do better than to quote the sententious utterance of a brilliant and witty French neurologist (E. Brissaud, Leçons sur les Maladies Nerveuses, Paris, 1895) upon this point: "I remain convinced that the surgery of the spinal cord is full of promises, just as hell is paved with good intentions."

ECHOES AND NEWS.

NEW YORK.

No Plague Yet in New York.—The "City of Rome" and the Allan Line steamer "State of Nebraska," both from Glasgow, show not the slightest trace of any bubonic plague.

Illegal Practicing.—An agent of the County Medican Society charged Louis Capobianca of No. 118 Forsyth Street, in the Essex Market Court with practising medicine without being registered. The defendant asserted that he received his diploma in Italy, and did not know that he would have to register in this country. He was held for trial.

Dr. Winters Injured.—Dr. Joseph E. Winters, in company with his daughter, were thrown from their carriage August 31st near Stockbridge. Miss Winters escaped with only slight bruises, but Dr. Winters' arm was broken in three places. Dr. Winters was taken to Council Grove, where he is staying, and Dr. McBurney was called to set his broken arm.

Dr. Williams Sandbagged. — Dr. Hamilton Williams, the Coroners' physician, was recently attacked by ruffians and seriously injured.

Yellow Fever in New York.—Ignacio Garcia, a steerage passenger on the Spanish steamer "Leon XIII.," which arrived September 2d, from Havana, was removed to-day to Swinburne Island for treatment and observation. Dr. Doty said Garcia showed symptoms indicating yellow fever. The steamer and her passengers were held at Quarantine for disinfection and to serve out the balance of the quarantine period of five days.

Bequest to Rochester Hospital.—The Rochester City Hospital stands a chance of receiving a bequest of $50,000 from the will of Judge Francis O. Mason of Geneva. By the terms of the will the sum of $50,000 is left to the Geneva Hospital under the express condition that the hospital shall not have an officer known as a chaplain or have any person in its service at any time any part of whose duties it shall be to perform such services as are usually performed by a chaplain. The will provides that in case such request is not complied with the bequest shall revert to the estate of the testator and then be given to the Rochester City Hospital. Not more than $10,000 of the sum is to be expended for buildings.

Novel Treatment for Hay-Fever.—An artist of this city spent an hour or so in a cold storage warehouse recently in order to obtain relief from a persistent attack of hay-fever. On coming out he found that his cheeks were frostbitten.

Stramonium Poisoning. — Poisoning from Jamestown weed, Datura Stramonium, seems to have its quota every fall. Two cases are reported this week from Brooklyn. George Lenz, four years old, who lived with his parents at No. 725 Douglass Street, died, and Joseph Johnson, of the same age, and living at the same address, is on the point of death. The little fellows went lately into the vacant lots on Eastern Parkway and are thought to have eaten the thorn apple."

Randall's Island Fire.—Painters working on the roof of the School for the Feeble-Minded on Randall's Island, Wednesday, dropped a live coal on the roof. When they stopped work at 5 o'clock the coal was smouldering, and ten minutes later the roof was on fire. The blaze was quickly discovered, and the island fire department soon had it extinguished. The damage was slight.

PHILADELPHIA.

Thief Caught in Hospital.—A discharged employee of the Pennsylvania Hospital recently climbed over the wall and was discovered by one of the resident physicians after he had stolen a watch and several pins. He confessed and admitted that he meant to steal.

Decision Against Compulsory Vaccination.—The law requiring vaccination of school children was upheld by a recent court opinion in this city. In Bradford County it has been decided that the law is not mandatory but optional. The son of a Christian Scientist was refused admission to a school because of non-vaccination. The school board then obtained a verdict for two dollars from the father, the penalty of non-attendance. A higher court reversed the decision as above stated.

Woman's Medical College.—The vacancy in the chair of Professor of the Principles and Practice of Surgery has been filled by the appointment of Dr. W. L. Rodman. Dr. W. V. Laws has been chosen Professor of Operative and Clinical Surgery. During the month of August 362 new patients were treated at the hospital.

Public Baths and Contagious Diseases.—The epidemic of catarrhal conjunctivitis in the city was believed to have been traced to the public baths by two hospitals, the Board of Health being notified to that effect. A medical inspection was ordered and the 9 baths found to be in a satisfactory condition as to disinfection and precautions taken against contagious diseases.

New Children's Hospital.—Germantown dedicated a new Children's Hospital September 3d. The building accommodates 25 patients, but this capacity will soon be doubled. The hospital is the outcome of the suggestion of a six-year-old girl who, a few days before her death, asked that seventy-one cents she had saved be used to start a hospital for children.

CHICAGO.

Fasting by Divine Command.—"Dr." Henry R. Wallace Andrews, a minister and veterinary surgeon, broke a fast of forty days, during which he ate no solid food of any kind, at the County Jail to-day. The meal after his long period of self-denial was composed of a slice of watermelon and a few ounces of sponge cake. He fasted in accord with a divine command.

Obituary.—Dr. Ernst Schmidt, of 424 North State Street, died at his home August 26th. He was for more than forty years one of the foremost physicians of the city, having been at the head of the consulting staff of the Alexian Brothers' Hospital for several years and having acted in the same capacity for the Michael Reese Hospital, the individual supervision of which had been intrusted to him by the founder. Dr.

Schmidt was born March 2, 1830, in the village of Ebern, Bavaria.

Discuss Lymph Cure.—Physicians from all parts of the country, members of the American Animal Therapy Association, the society organized in New York in September last by Dr. Joseph R. Hawley of this city, met here August 29th and 30th, to discuss primarily the latest developments in the Roberts-Hawley goat-lymph compound and thyroid extract, and incidentally all forms of animal lymph. The cure of septic diseases of a chronic nature by the use of lymph made from the lymphatic glands of goats is at present attracting the attention of the entire medical world, by reason of the success attained. Particularly good results have been obtained in cases of local paralysis, locomotor ataxia, certain forms of insanity and premature decay and old age.

Trinity Diet-Kitchen for Infants.—Dr. George T. Palmer, medical director of the Trinity Diet-Kitchen for Infants, has just issued a report, showing the work of that institution during the last two months. He reports almost 700 babies cared for and only one death. The low death-rate is attributed by Dr. Palmer to the high grade of milk and foods given out, to the purity of the spring-water supplied, and to the ice that has been given to all to preserve the food.

The Norwegian Hospital.—On August 22d a lawn-party and musical and literary program were given for the benefit of the Norwegian (Tabitha) Hospital.

State Board on Lodging-Houses.—The Committee of the State Board and its Chicago inspector will ask the Board to draft a law for governing the lodging-houses more like the law now in operation in New York City. This law will include more rigid sanitary regulations, which, if enacted and enforced, should take away Chicago's reproach in this regard.

GENERAL.

Plague in Glasgow.—Present reports indicate 13 doubtful cases in the hospital and 103 suspicious persons under observation.

Yellow Fever in Senegal.—The mortality has been excessive. Fifteen per cent. of the population has been destroyed. One per cent. of the population are dying every day. The sick live only three to four days. Of those affected the mortality is eighty-six per cent. The physicians are suffering as much as the rest of the population. Negro priests, who are immune, are alone left to give the last religious rites.

Obituary.—First Lieut. Easton Burchard, Assistant Surgeon, Fortieth Infantry, died of dysentery contracted in the line of duty, on September 2d, on the transport "Grant." He was born at Bonnot's Mill, Mo., on March 29, 1865. He entered the service as Assistant Surgeon of the Fifth Missouri Volunteers on May 4, 1898, and was appointed First Lieutenant and Assistant Surgeon in the Fortieth Infantry on August 17, 1899.

A $10,000 Fee.—Arthur Goebel, brother of the dead Governor and his devisee under the will, has placed a claim against the estate of Gov. Goebel for $10,000 for Dr. McCormack's services. Gov. Goebel and Dr. McCormack had long been close friends and when Goebel was shot Dr. McCormack, who happened to be in Frankfort at the time, was one of the first physicians to come to his assistance. The wound was mortal, but knowing that if life could be prolonged a few days the Legislature would decide the contest, and that in the state of feeling resulting from the assassination Goebel would probably be declared Governor, Dr. McCormack took every step known to science to maintain life. Dr. McCormack refused to render any account for his services on the ground of personal friendship.

Kafir Cure for Dysentery.—It is reported that several of the army surgeons have tried the Kafir cure for dysentery with marked success in some very bad cases. It consists of a decoction of the root of the pelargonium or geranium. There are upward of 150 different kinds of wild geranium in South Africa, and each seems equally efficacious in cutting short an attack of dysentery. The Kafirs and Zulus simply chew the geranium root, but a more elegant preparation is made by boiling the root in milk. One or two tablespoonfuls are given every two hours till all symptoms of dysentery have disappeared. It would be desirable to obtain the name of the species. Our native geraniums, while having a mild astringent action, are not very efficacious in dysentery.

Cholera Spreading in India.—The Committee of One Hundred on India Famine Relief received the following cablegram September 4th, from William T. Fee, United States Consul at Bombay, Chairman of the Americo-Indian Famine Relief Committee: "In spite of previous rainfalls the situation is again alarming. Crops are beginning to wither. Great anxiety is felt lest they be destroyed. Starvation still threatens. Money is needed for buying food, as well as clothing. The ravages of cholera are increasing. Let America maintain her splendid benevolence. The need is undiminished." The Committee acknowledged the receipt yesterday of additional subscriptions amounting to $1,071.05, which makes the total of the fund to date $227,290.88.

To Colonize Vegetarians.—The Rev. H. S. Clubb of Philadelphia, President of the Vegetarian Society of America, is at Chattanooga, Tenn., in the interests of this society. The members are scattered all over the United States, and

during the last four years, so President Clubb states, there has been a growing spirit among the greater part of its members to separate themselves more distinctly from the rest of society. It is with this spirit that his journey has been made to the South. He is now in search of a suitable place for colonization. What he wants is a place where all kinds of fruits and vegetables can be grown on an extensive scale. This being found the scheme is to colonize the vegetarians and to engage in extensive fruit-farming for the Northern markets. Along with this the industry of making and selling peanut butter will be pushed.

Consanguineous Marriages and Consumption.—Dr. C. A. Davies of the Isle of Man in a recent communication to the British Medical Association said: Consanguinity in marriage among the Manx people had led to much illness in the offspring. There has been little crossing of races among them since the twelfth century, and a custom exists on the island to-day of discouraging marriages between persons living in different parishes. Hence there exists all over the island a condition of close "inbreeding." As a consequence the general death-rate from consumption is 25.70 per 10,000, double that of England and Wales. In Lonan, an isolated part, where all of the inhabitants of the parish have only three or four surnames, the rate is 41.79 per 10,000, while in Peel, where many more strangers come, it is only 15.19.

Statistical Study.—The members of an International Commission, with delegates from every European country and America, which meet at the Paris School of Medicine this past week, have decided to recommend to their respective Governments an international system of nomenclature in classifying the causes of deaths, for the purpose of rendering comparison possible between the death statistics of the civilized countries. The system recommended is that of Prof. Bertillon, whose anthropometrical method for the identification of criminals is in use by the police of the civilized world, the chief reason assigned for this choice being that the French classification is already in use in North and South America, and in several European countries. The recommendation, if adopted, will take effect January 1, 1901. There was only one dissentient to the recommendation, the delegate from Germany.

Typhoid in Newark.—The local board of health in tracing the many cases of typhoid fever recently reported has found that a large percentage of the victims are girls employed in the Clark thread mills, in this city and Kearny. Investigation showed that these girls have been drinking considerable water taken from driven wells in the mill yards. When Bacteriologist Connolly examined the water he found that, while that taken from the well at the mill on the west side of the Passaic River was fairly good, that taken from the wells in Kearny, on the east bank of the Passaic, was badly infected.

Decreasing Birth-Rate in Europe.—New statistics demonstrate the fact that in all the countries of Europe, with the exception of Russia, the percentage of increase by births has been diminishing since 1891, the average decline being three per cent. The greatest difference is shown by England, where births have receded from 34 per cent. to 29.1 per cent., and the smallest by Norway, namely, 0.1 per cent. From 1871 to 1875 the increase by birth in Germany was 39.9 per cent., but in 1891-95 this had sunk to 36.3 per cent., and in the year 1897 it went down to 36 per cent. The general average from 1881 to 1885 was 36.8 per cent., but is now 36 per cent. More noteworthy is the decrease in Austria where in the course of twenty-five years it has dropped from 39.5 per cent. to 37.4. In Belgium the percentage in 1871 was still 32.1, but in 1897 only 29; and in France the shrinkage in the same period was from 25.5 to 22.4. Next to Norway the most favorable data are reported from Switzerland.

Typhoid in Paris.—The official medical bulletin this past week reveals a disquieting sanitary situation in Paris. Statistics show that typhoid fever prevails in an almost epidemic form. There were recorded from the beginning of the year to August 13th 3,148 cases, of which 568 resulted fatally. This is a considerable increase over the records of previous years. Paris is never free from this disease, but until 1898 the number of cases for the corresponding period did not exceed 700. Moreover, the figures for the last few weeks of the present year show a perceptible increase over those of the earlier period. The prevalence and spread of typhoid are due entirely to bad water. One of the sources from which Paris is furnished is known to be infected with the typhoid bacillus, though the water from all the others is perfectly pure. The authorities, however, declare that they are compelled to utilize the contaminated source because the others are inadequate.

More Surgeons Needed in Philippines.—Many posts in that tropical climate are now without doctors. The number of military stations has been increased from 125 to 375 since last January. Although the sick report is phenomenally small, being less than 9 per cent. of the effective force, the large number of stations occupied and the increased amount of executive and administrative work that must be done in addition to the hospitals require at least one doctor for every post of any appreciable size in addition to those required for the administration personnel. At present there are but 366 medical officers for the entire work, including those with the "Relief" and those on duty in China. The result is that there is a large number of posts without any medical attendance except such as is furnished by members of the hospital corps, while a con-

siderable number of stations have no medical attendance of any kind.

Poisoned by Eating Crabs.—Five persons were poisoned in Peekskill, N. Y., Wednesday, 5th, by eating crabs. They were Mr. and Mrs. Edward J. Cole of No. 113 Union Avenue and their three guests. Mr. and Mrs. Cole and a Mr. Tate were unconscious all night, and were still very ill this morning.

Elmira Reformatory Appointment.—Announcement was made September 5th by the State Civil Service Commission that William W. Simcoe of Elmira had been appointed from the civil service eligible lists as keeper and captain at the Elmira Reformatory, at an annual salary of $3500 and board allowance.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, August 25, 1900.

ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION — ADDRESS ON OBSTETRICS — THE ABANDONMENT OF ROUTINE VAGINAL EXAMINATIONS THE GREATEST ADVANCE IN MIDWIFERY — OCULAR HEADACHES — PNEUMONIA IN CHILDREN—SOUTH AFRICAN WAR COMMISSION—THE DEADLY "RED TAPE" DODGED BY MR. RUDYARD KIPLING—ANNUAL CONGRESS OF THE ROYAL INSTITUTE OF PUBLIC HEALTH—ATTACK ON THE GOVERNMENT FOR THE FAILURE TO PROVIDE SANITARY OFFICERS IN THE SOUTH AFRICAN WAR—THE DANGERS OF RAILWAY CARRIAGES—TUBERCLE BACILLI IN THE DUST—WATERTIGHT SCHOOLS.

At the annual meeting of the British Medical Association Dr. William J. Smyly of Dublin delivered a highly important and practical address in obstetrics on "Maternal Mortality in Childbed." In a rapid historical survey of the subject he said that obstetricians in the past pursued their work in the face of failure little short of disastrous. In the first half of the present century the mortality, especially in hospitals, was probably greater than at any other period of the world's history. But toward the close of the seventies improvement suddenly occurred. In the Paris Maternity, for example, the mortality dropped in one year from 8 to 4 per cent., and in 1881 to 1 per cent., and has since improved. At the Rotunda Hospital during the period 1870-1876 1 in 45.5 women confined died; from 1890-1896, 1 in 181.7. In 1870 antiseptic principles were first applied to obstetrics, but the original system was too cumbrous for general practice. Then the spray was replaced by the douche and the vagina was douched before and after every labor; soon the uterus was included in the process. But accidents and even death, due to injection of air or antiseptic fluid into the veins, began to multiply and even an outbreak of puerperal fever was traced to the douche in the Berlin Charité Hospital. Leopold showed that by thorough disinfection of the external parts and avoidance of unnecessary examinations better results were obtainable than by prophylactic douching. The teaching of Semmelweis and Sir James Simpson that infection is chiefly carried by the hands of the attendants is now generally accepted. No handling, no sepsis, was not far from the truth. Leopold had shown that patients delivered without vaginal interference made better convalescence than under the most scrupulous antiseptic precautions. Both experience and bacteriology showed that absolutely aseptic hands could not be insured by any known process. The best practice was to substitute external examination for the vaginal, which Dr. Smyly claimed was the most important advance in modern midwifery. It is impossible to exaggerate the far-reaching importance of this statement which is a direct impeachment of the current practice in obstetrics all over the world, of a procedure which must be performed hundreds of thousands of times every day and to which every pregnant woman is exposed, and this by a past master of the Rotunda Hospital, speaking with all the authority of the great Dublin School of Obstetrics and at the most important medical congress in the British Empire. But Dr. Smyly went further and claimed not only that external examination was safer than vaginal, but also that it was more useful in diagnosis. At first he found it difficult to believe this, having for years practiced the ordinary method. By external examination he said the presentation and position of the fetus, whether it was living, dying or dead, may be ascertained and the course of the labor followed. Pelvic deformity was suggested by pendulous abdomen, abnormal mobility and obliquity of the uterus. In prolonged labors material danger was indicated by thickening of the upper and thinning of the lower uterine segments, elevation of the contraction ring and prominence of one or both round ligaments.

In the Section on Ophthalmology Mr. W. A. Brailey delivered an introductory address on "Ocular Headaches." Accommodative movements were bound up with the great majority of ocular headaches. It was a general law that the larger the ocular error the less the effect produced on the head, because a great defect of accommodative power led to its abandonment, the patient seeing as best he could without it. So also uncorrected presbyopia rarely caused headache except just at its commencement. Spasm and headache were more easily produced by moderate inequality of refraction, especially if astigmatic, and most of all by astigmatism with asymmetry of the axes. Errors of the external muscles produced headache but less often than errors of the accommodative muscles, although more often migraine, giddiness and general distress.

In the Section on Laryngology Dr. Scanes Spicer read an important paper on "Nasal Obstruction." An obstruction to the inspiratory current through the nose necessarily produced a fall of air tension and "dry cupping" of the mucous membrane of the nose and the accessory sinuses. This led the speaker to regard nasal stenosis as a preeminent factor in the etiology of catarrhal throat, nose and ear processes, which he found was borne out by clinical experience. It often happened that the most diverse cases of nasal obstruction were sent to him for operation for adenoids in which adenoid hypertrophy was absent or insignificant. In most cases of adenoids the condition was only a part, and often a small part, in the pathological condition of the so-called adenoid child, fractured and deflected nasal bones and cartilages, turbinal enlargements, hypertrophied tonsils, pushing up and growing up behind the soft palate, stunted nostrils and even vaulted palate were often more important features. The operation for adenoids or nasal obstruction was often incorrectly regarded as the termination of the case. It was only the first step. Developmental and respiratory exercises for the expansion of the chest and the restoration of respiratory vigor required attention.

Dr. Nestor Tirard (London) read a very able and lucid paper on "The Nature and Varieties of Pneumonia in Children." Bronchopneumonia had attracted more attention in children than lobar pneumonia. The distinction was not well defined between bronchopneumonia and vesicular bronchitis. Bronchopneumonia was common up to the age of three, after that many cases conformed to the type of true lobar pneumonia. The extent of lung engorgement was greater in children than in adults and this probably was responsible for the confusion with bronchopneumonia. As to abnormal forms the temperature might be extraordinarily high, say up to 106° F., either at the beginning or just before the crisis; there might be an unusually sharp crisis and a fall of 9°, 10° or 11.5° F.; and there might be wide oscillations of temperature, 5° of difference between the night and morning temperatures, which was apt to confuse diagnosis. The initial symptoms were occasionally like those of tuberculosis meningitis—headache, squint, retraction of the head and vomiting; or the sickness and delirium might suggest cerebral tumor. In spite of all the symptoms of pneumonia physical signs might be absent. In two cases quoted the dulness and tubular breathing appeared only at the crisis.

Very little fresh evidence of a usual character and calling for any remarks has been taken by the South African Hospital Commission since my last communication. The Commission has now sailed for South Africa, where they will pursue their inquiries. They will be away two or three months; on returning to England fresh evidence will be taken. The evidence of Mr. Rudyard Kipling shows the deadly influence of "red tape" in army organization, and his method of evading it is interesting. He visited the Cape-town hospitals and the doctors told him they had everything they wanted and the hospitals were by no means full. He then went to the nurse and asked her if she wanted anything, saying, "Because I can get things out of the 'Absent-Minded Beggar Fund.'" The reply was, 'We want pyjamas. Don't bring them to the Store Issue Department but to the back-door.' So I got 98 pairs of pyjamas, unloaded them at the back entrance and gave them quietly to the nurse." At another hospital he asked the same question and received the same answer—that it was no use taking things to the officials, but that if he brought pyjamas and pillow-slips to the back entrance they would be obliged, because these were wanted.

The Royal Institute of Public Health has held a very important annual Congress at Aberdeen attended by delegates representing the principal sanitary and municipal bodies throughout the United Kingdom. The President, Lord Aberdeen, said that sanitary legislation dated only from a hundred years ago when Factory Acts were passed for the protection of children, who were often herded together promiscuously within the actual factory building, and for restricting the age of employment to those above eight. Acts to prevent contamination of water supply with sewage followed. In 1846 powers were given to a central authority—the Privy Council—to issue orders for preventing the spread of disease. In 1889 the Infectious Disease Notification Act was passed. The work of the Congress was so extensive that it had to be taken in different sections—Bacteriology and Comparative Pathology, Chemistry and Meteorology, Architecture and Engineering, Municipal and Parliamentary Hygiene, Preventive Medicine and Vital Statistics. In the last section Prof. Simpson of King's College, London, made a violent attack on the Government in connection with the South African scandal. After the experience of the Crimean war, he said, it was discouraging to find that 1 in 20 of the soldiers suffered from a more or less preventible disease, typhoid fever. There was a serious defect in the sanitary administration in South Africa. In the Afghan and Egyptian campaigns sanitary officers were appointed. In the latter dead camels and other transport animals were burned and there was very little typhoid and practically no ophthalmia. But in the present war no sanitary officers had been appointed, although Sir Walter Foster had pointed out the necessity. Never before had greater attention been paid to the sick and wounded, but the same solicitude had not been paid to prevention of disease. He attached no blame to the Army Medical Service, which could not perform impossibilities. They were working under pressure, one was required to do the work of two. A lesson might be taken from the Germans, their force going to China was accompanied by a special sanitary service. Since

1892 no sanitary officer had been appointed at Aldershot. Sanitary work was now attended to by quartermasters.

Prof. Hamilton of Aberdeen read a paper on "The Danger of Spreading Disease by Vehicles of Transport." The danger of spreading disease by dust impurities was not properly grasped. He confessed that he had a feeling of horror on entering a railway carriage, school or place of public resort. He had made a number of experiments with the dust taken from the floors of railway carriages. Two out of twelve samples were contaminated by the tubercle bacillus. The so-called cleaning of carriages consisted merely in stirring up dust. To guard against the spread of disease the flooring should be movable and the cushions detachable, and the carriages should be periodically disinfected. People will spit on the floor in spite of everything done to prevent it. The sputum might contain the organisms of tuberculosis, pneumonia, diphtheria or influenza, which after drying became disseminated in the dust. At present railway companies studiously washed the outside of carriages, washing of the inside has yet to come. He thought that schools ought to be watertight compartments, the walls and ceilings covered with watertight cement, and the roof and flooring similarly waterproof, and that every schoolroom ought to be hosed or otherwise cleansed once a week.

A CASE OF POLYNEURITIS—LINGUAL GANGRENE—THE FACIAL NERVE AND WEEPING—SPINAL-CORD TUMOR—MARRIAGE AMONG THE TUBERCULOUS — DIGESTIVE LEUCOCYTOSIS — PRODUCTION OF MILK—RUPTURE OF THE UTERUS—HEMOSTASIS AND FAT EMBOLISM — GUNSHOT WOUND OF THE HEAD WITHOUT SYMPTOMS—DOUBLE ANKYLOSIS OF THE HIP—TUBERCULOSIS OF THE STERNUM—FOREIGN BODY IN THE ESOPHAGUS—IN THE RECTUM.

Ewald, at the Gesellschaft der Charité-Aerzte in Berlin, June 28, presented a patient with malarial polyneuritis. He had moderate paralysis of both lower extremities, especially of the extension of the great toes, together with a psychosis manifested by failure to articulate and remember. After this case he discussed another which had a most obstinate fever of the tertiary type, which resisted all known methods of treatment.

Werner, at the Aerztlicher Verein in Hamburg, June 26th, exhibited a case of traumatic lingual gangrene. This patient, a prostitute, had probably acquired syphilis, which never within her observation or memory had given florid signs and which, therefore, had never received any systematic medical attention. In consequence of this infection a frank attack of tabes dorsalis began about a year previously and latterly had gone on to mental aberration, showing foolishness, weird imagination, utter falseness and various voice changes. The last development had been gangrene of the tongue, due to hysterical self-damaging tendencies. Frequent and persistent biting had been manifest. The area affected was the anterior third. The tongue had separated along a line of imprint made by the teeth and the gangrenous part had come away in masses, leaving a clean stump.

Sanger showed a sixteen-year-old boy, who by a fall from a wagon had received a fracture of the base of the skull on the left side. It was followed by paralysis of the auditory and of the facial nerves, the latter in all its branches; later there was disturbance of taste in the anterior third of the left lateral half of the tongue and some weakness at the base of the tongue on the same side. But tears flowed equally well from each eye. The point of the case seems to be that the tear function is under control of the trigeminus, facial and sympathetic nerves and that the supposition that the facial alone supplies it is probably not correct.

Bottiger reported a successful case of removal of a tumor of the spinal cord. The patient was sixty-five years old and had complained of pain, increasing in severity and distribution, in the left leg and of paresis with pain in the right lower extremity with a zone of analgesia about the hip. At the operation the arches of the fifth to the tenth dorsal vertebræ were removed and the dura exposed. An extradural psammoma was found. The wound healed well and all the prospects were for a good recovery.

Gerhardt at the Verein für innere Medicin in Berlin, July 2d, discussed the propriety of marriage of the tuberculous. The question had come up late during the last Tuberculosis Congress with insufficient time for its ripe consideration. Literature is full of papers on this subject, aiming to give opinions and guidance to the family practitioner in advising about this all important question. It appears that the consensus of opinion makes marriage worse for the woman than for the man, because she is oftener infected through sexual intercourse. The reason for this is that in a large proportion of tuberculous males the sexual apparatus is involved and in about 5 per cent. of all cases examined the same condition is true. Weber examined 68 persons; of 39 healthy males probably 1 had been infected by his wife; of 29 females 18 traced their infection to intercourse and half of these in wedlock. One tuberculous man lost four, and a second three wives by his own infection, all seven dying eighteen months after marriage. Virchow long has taught that after marriage a previously existing tuberculosis is apt to get worse, and that males of tuberculous families are apt to go to pieces soon after marriage. The drain of pregnancy and lactation is much increased by the presence of tuberculosis and for

the child this too adds a very great danger. Practically a good rule would be for a victim to abstain from marriage at least one year after apparent cure. In this connection Virchow relates the case of a young physician who was considered cured of the disease, had remained some time in a trying climate and finally married. His tuberculosis returned soon after and resulted fatally. Another practically important and difficult question deals with the interference with pregnancy owing to tuberculosis. If the disease is steadily progressing, the author thought this should be done. In his experience digitalis in slowly increasing doses is a very good treatment for the frequent abnormal sexual appetite so common in tubercular males, and often satiated by pollution. Sometimes gonorrhea or syphilis may be superimposed upon the tuberculosis. Appropriate treatment will eliminate either from the diagnostic or therapeutic aspect of the case.

FURBRINGER criticised the view of the speaker as too discouraging, and added that he had seen tuberculous men positively improve under the quiet of married life, in contrast with excesses of unmarried life.

JAPHA read the report of his experiments on himself as to digestion leucocytosis. He found that a greater increase in the white cells occurs after dinner than after the other meals, for instance breakfast, although of food rich or poor in albumen. He also determined that when fasting after midday a leucocytosis occurs. This he deems due to the daily influence of food ingestion. The increase is chiefly in the polynuclear cells. The supposition formerly held that these cells proceed from the intestinal wall is to be abandoned because they are of the mononuclear variety. Here also falls to the ground the theory that they originate directly out of the absorbed peptone in the intestinal wall. In his opinion they come directly from the bone marrow and their appearance is merely the expression of digestive activity. Apparently the diagnostic value of this condition is not great and depends upon whether or not this variation can be further established.

WASSERMANN, quoting the results of experiments by Bordet, said that serum of one kind of animal injected into another bestows upon the latter blood its characteristics. Again, milk injected into the circulation of an animal will determine upon the milk of that animal many of its own features. It is a well-known fact that the albumin in the milk of many animals varies widely from species to species. If cooked milk is injected the experiment fails utterly. From these premises it seems possible in this way to practically duplicate human milk.

FUNKE at the Unterelsässischer Aerzteverein, June 23d, read the history of a recovery from laparotomy for rupture of the uterus, as follows Primipara, aged twenty-one years, at term; at the beginning of labor the head of the living child impacted in the pelvic canal high up; finally still birth by asphyxia; apparently good condition of the mother; no placenta delivered; examination showed rupture of the uterus and induced syncope and collapse; laparotomy at once; placenta removed from the abdominal cavity; toilet of the peritoneum; suture of the rupture which extended laterally from broad to broad ligament in front; drainage through the cervix first provided for; very careful suture of the peritoneal coat; closure of the abdomen. The speaker considered the careful suture of the peritoneum the most important detail and the above treatment the best.

RECKLINGHAUSEN reviewed the literature on traumatic hemastasis and fat embolism with the reports of Perthes, Willers, Huete, Vogt and Braun, of the universal hemorrhagic infiltration of the head, neck and shoulders without any deep or external hemorrhage of importance after tremendous pressure about the thorax and abdomen. He then presented the organs of a fifteen-year-old boy crushed in a wheel about the upper part of the chest. The eighth and eleventh ribs were bowed inward; the eighth and ninth were broken at their angles; the last two thoracic and the first three lumbar vertebral arches were broken and the peritoneum torn off; hemorrhage into the fatty tissue of the spinal canal; protruding eyeballs; thick ecchymosis and hemorrhagic infiltration of the skin of the head, neck and shoulders, into the mucosa of the throat and temporal muscle tissues, subpleural and pulmonary ecchymosis and pulmonary fatty embolism apparently from the subcutaneous regions; no cutaneous external hemorrhage, except through abrasions. The conditions seemed limited to the veins and especially to those which have no valves. The cause of these hemorrhages seems, first, the sudden pressure arrest of the blood-current with damming back of the blood, and, second, actual bursting of the small veins not provided with valves.

NAUNYN in the discussion said the infrequency of valves anywhere in the veins favored such conditions. Even the vena cava has no valves until it enters into the heart.

BRAUN contributed at the Altonaer Aerztlicher Verein, April 25th, a case of gunshot wound of the left temporal bone without cerebral symptoms, either primary or secondary. Upon opening the scalp-wound the bone was found shattered over an area the size of a dollar and deeply depressed. The fragments were all removed. Those of the inner table were more numerous and smaller than those of the outer and crowded under the firm bone margins. The bullet was found flattened out between the dura and the cranium. The membranes were intact and the brain pulsated normally. No complications occurred. He also exhibited the brain and left petrosal bone of a twenty-five-year-old man operated on for abcess of the cerebellum. The origin of the disease

was evidently middle-ear lesion and the diagnosis of meningitis was excluded, because the pulse showed pressure and the temperature was subnormal. Somnolence came on and von Bergmann laid the temporal bone bare and entered the brain in the left temporal lobe along the lowest temporal convolution. Pus was not found. The bone-wound was then extended backward to the angle between the sigmoid and transverse sinus. A small abcess cavity situated far in near the bone was evacuated and drained. At the autopsy meningitis was not found; the abcess was in the left lobe of the cerebellum in the angle between the tentorium and the petrosal bone. The middle ear had been destroyed and the facial nerve and canalis Fallopii directly infected. At the meeting of May 16th he introduced two women both operated on four weeks previously on the same day for ruptured ectopic gestation. Internal hemorrhage threatened life. At the laparotomies the arteries were tied off and bleeding ceased; the sacs were then ablated and the clots and blood washed out of the abdomen. Drainage was put in and the wounds closed. All went well until after a few days fecal vomiting appeared, but this was of short duration and yielded to lavage. Full prompt recovery then resulted.

Krause exhibited a fourteen-year-old girl with double hip ankylosis secondary to purulent arthritis. Through a Langenbeck incision the left femur was severed just through the great trochanter, the end of the distal piece carefully rounded and the proximal fixed portion hollowed out for a false joint. It is hoped that early passive motion will facilitate such joint-formation. The primary dressing was plaster-of-Paris and the position midway between adduction and abduction. He also brought forward a forty-one-year-old woman who had suffered removal of the manubrium sterni and the inner halves of the clavicles for tuberculosis. Complete cure without sacrifice of function of the upper extremity followed.

Wilms at the Medical Society, Leipzig, May 8th, showed a two-and-a-half-year-old child who had undergone external esophagotomy for impacted foreign body. A coin had been swallowed long previously, was easily palpable externally, so fixed as to render extraction through the mouth impossible, and through the wound only after much rather vigorous manipulation. The wound was packed, the esophagus not sewn. Healing occurred down to a very small fistula in three weeks, which itself closed in a few days. Feeding was carried on by stomach-tube carefully passed through the nose. In connection with the above he recalled a case of instructive and curious force illustrating the tolerance of the body for foreign bodies. A laborer still pursuing his avocation presented himself at the clinic August 20, 1899, complaining of rectal obstruction. Examination showed a knife-blade whose handle was palpable in the sigmoid between the navel and the symphysis. He had passed the knife into his rectum with suicidal intent on July 20, 1899. The instrument had bored quite a cavity in the sacrum, and was fixed therein. Easy removal and prompt recovery followed.

SOCIETY PROCEEDINGS.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

Held at Paris, August 2-9, 1900.

(Continued from page 355.)

Section on Pharmacology, Materia Medica and Therapeutics.

Digitalis: Its Pharmacology.—The physiological and therapeutical uses of digitalis were discussed by Dr. Lauder Brunton. He first gave a historical résumé of the drug and brought out the apparent differences in its action on the heart of lower animals and of mammals. In the frog the cardiac beats are lessened in number and the contractions are more complete. The heart expands more in diastole and contracts more in systole. In mammals also the cardiac pulsations become slower and more powerful, but in them this slowing of the heart's action is not due alone to its action on the muscular tissue of the heart, as it is with the frog, but is due to stimulation of the cardio-inhibitory center in the medulla. There is a general consensus of opinion regarding the power of digitalis to increase the strength of the cardiac contractions; but this is not the case in regard to its action on the blood-vessels, for some maintain that its action in contracting the blood-vessels is as marked and is an important factor in the action of digitalis, while others maintain that the contraction of the vessels which it produces, if any such contraction exist at all, is slight, transient, and unimportant. Dr. Brunton's view is that contraction of the vessels produced by digitalis in mammals is very well marked, and depends, just as in the case of the heart, partly upon a peripheral and partly upon a central action of the drug. Digitalis has a local action in the muscular walls of the arterioles, causing them to contract, and it also stimulates the vasomotor center in the medulla oblongata. By its combined action of contracting the arterioles and of increasing the power of the heart it raises blood pressure.

Digitalis: Kidney Action.—The diuresis which digitalis produces is probably due to increased pressure within the glomeruli of the kidneys. Digitalis causes contraction of the vessels of the kidney as well as other parts of the body. At one stage of the action of digitalis, when the blood-pressure is very much raised, the secretion of urine may be as completely arrested as if the renal artery were tied. As the pressure begins to fall the secretion of urine becomes greatly increased, but the urine generally shows a trace of albumin exactly in the same way as if the renal

artery were first tied and then the ligature removed. If the pressure in the vessels is naturally high, and the secretion of urine abundant, it could hardly be expected that it would be much increased by the action of digitalis; but if the blood pressure is low, as in people with lax arteries, or where the arterial system is comparatively empty in consequence of mitral regurgitation, the diuretic effect of digitalis is naturally more pronounced.

Digitalis: Its Chemical Composition.—The chemical composition of digitalis is complex, and a good deal of the discordant results obtained by different observers are not only due to differences in the animals experimented upon, but to differences in the physiological action of the preparations employed, even when these preparations have borne the same name. According to Schmiedeberg, the chief components of digitalis are digitoxin, digitalin, digitalein, digitonin, and digitin. Digitin has little or no physiological action, and digitonin but little, so at present both may be dismissed from consideration. The crystallized digitalin of Nativelle consists chiefly of digitoxin, the digitalin of Homolle and Quevenne consists chiefly of digitalin and German digitalin consists chiefly of digitalein and digitonin. The action of these drugs appears to be nearly alike in kind but different in degree, digitoxin being by far the strongest. Nativelle's digitalin, which consists chiefly of digitoxin, was found by Widal to be eight or ten times stronger than amorphous digitalin. Nativelle's digitalin in daily doses of 1 to 2 milligrammes slows the pulse, while 3 to 10 milligrammes of Homolle's digitalin are required for this purpose. The German digitalein may be given in doses three times as great as Homolle's digitalin, or ten times as great as that of Nativelle's.

Digitalis: Therapy.—The therapeutic actions of digitalis or of its active principles are that they (1) regulate the heart's action; (2) assist the falling circulation; and (3) act as diuretics. In cases of palpitation and functional irregularities of rhythm without organic disease, small doses of digitalis, such as five to ten minims of tincture, are sometimes very useful. The good effect of digitalis is well marked in cases of palpitation which have come on from physical strain, as by lifting heavy weights, or from anxiety and worry. In cases where the palpitation arises reflexly from irritation of the stomach better results are obtained by bismuth and rhubarb than by any cardiac tonics, although the addition of nux vomica to these two drugs assists their action. In cases of aortic regurgitation where compensation is complete, digitalis is quite unnecessary. In aortic regurgitation with full compensation digitalis may possibly be harmful, as the risk in such cases arises from fatal syncope. For the blood in the arterial system being in aortic regurgitation emptied backward into the heart as well as forward through the arterioles into the veins, the blood-pressure tends to become very low during the cardiac diastole. Should this diastole be prolonged the pressure may sink much below the normal, and the risk of syncope is increased. But digitalis is of the utmost service when the mitral valves become incompetent, either in consequence of damage to the valves themselves or in consequence of dilatation of the cardiac orifices from weakness after infective diseases, such as influenza, or from failure of the hypertrophy consequent upon aortic regurgitation or renal disease. To get the best results in severe cases the use of the drug should be associated with rest in bed and massage. The absence of exertion tends to lower the pressure which the heart has to overcome in systole, and lessens the rapidity of the cardiac beats. The slowness of the pulsation produced by rest is still further increased by digitalis. It is during diastole that the heart has time to recuperate. It is what might be termed the heart's period of rest, sleep, and repair, and by prolonging it one tends to restore the heart to its normal condition. In fact the empty arteries tend to fill, the distended veins tend to become empty, and the venous congestion which led to enlargement of the liver, indigestion, flatulence, edema of the legs, and albuminuria, tends to disappear. The legs become normal in size, the enlarged liver becomes smaller, the digestion improves, the urine becomes abundant and free from albumen. The pulmonary circulation also becomes freer, the shortness of breath and irritating cough become less and less and finally disappear. The dilated heart being able to contract more powerfully, the ventricular and auricular orifices become smaller, and the valves even though they may be damaged will tend to close the orifices more completely during systole and thus lessen regurgitation. In addition to this the increased force of the cardiac beats tends to oxidize the tissues more completely.

Massage with Digitalis.—By the use of massage in addition to digitalis a good deal of work may be taken off the heart because, instead of having to drive the blood right round from ventricle to auricle, it will only have to drive the blood to the periphery, the movements of the masseur returning a great deal of both blood and lymph from the periphery to the heart.

Dangers of Digitalis.—Dr. Brunton spoke of the dangers of digitalis in cases of fatty heart and very high tension. He said that it has been said with much truth that it is by no means easy to ascertain with certainty that the heart in any patient has undergone fatty degeneration; but when the heart beats are feeble and its sounds are weak, disproportionately to the size of the organ, it is well to be on guard against possible injury from digitalis. If digitalis causes contraction of the arteries as well as of the heart, and the heart has undergone fatty degeneration while the muscular fibers of the arterioles have not done so, the resistance to the cardiac contractions will be increased, and a heart which is already hardly able to carry on the circulation

may be still further hampered by the drug. In such cases, if it is desirable to stimulate the heart by digitalis, the resistance in the arterioles ought to be lessened by the simultaneous administration of nitrites, such as nitroglycerin, nitroerythrol, or ethyl nitrite. The same precaution should be adopted in cases where the arterial tension is high, and the heart is just beginning to fail; but in such cases the risk may arise from the already high tension being increased and leading to a rupture of a vessel in the brain should be remembered. In such cases it may be well to avoid digitalis altogether; but should it from any reason be thought advisable to use the drug, not only should nitrites be given at the same time, but great attention should be paid to the condition of the bowels and liver. There is still an enormous field for investigation in regard to the action of drugs in combination, and although it is not known why the administration of mercury and calomel along with digitalis should greatly increase the utility of the drug, there can be no doubt whatever that this is the case, and that when digitalis alone fails to produce the result desired, it will frequently act most efficiently if mercury be given with it.

Surgical Treatment of Anasarca.—Dr. Menko (Amsterdam) spoke of the difficulties in the medical treatment of anasarca. In those cases in which diuretic, purgative, and diaphoretic treatment has proven unavailing he advocated surgical procedures. That this method has not proven popular it is easy to conceive, since the initial cause of the dropsy is one not amenable, as a rule, to methods of removal. Two surgical procedures are advocated, incision and drainage. Menko employs incisions for those patients who are agitated or delirious, for those who are unable to remain quietly in bed because of orthopnea, also in cases of sclerosis of the skin, induced by persistent edema. Drainage is preferred in all other cases. Somewhat modified Curschmann's cannulas were employed. Several favorable results were reported.

Section on Bacteriology and Parasitic Diseases.

Toxins and Antitoxins.—Ehrlich of Berlin presented a lengthy discussion on this subject. Toxins, he said, were very unstable substances found in animal and vegetable secretions after a certain amount of chemical breakdown. At the present time no definite chemical definition could be given of this group, as a whole, although many isolated members were chemically analyzable. Many of the toxins are obtained in too minute quantities to permit of analyses and the precise structure of many is hard to obtain, because of the many closely allied bodies found with them. The main proof of a toxin was its biological action. This action being manifested by the physiological action and the bodily reaction, under poisoning, which often results in the formation of some antitoxin body. In order to more correctly define a toxin, notwithstanding the chemical difficulties, a special incubation period was noticeable, in which direction certain analogies exist with the snake poisons. Ehrlich does not believe in the production of antitoxins for certain definite compounds, many of the alkaloids, for instance. The averred results in antitoxin production by morphine, he believes to be erroneous. Toxins form certain specific combinations with protoplasm and thus act in a manner different from that of other poisons. The alkaloids are thought to bring about phenomena in living protoplasm, akin to what chemists term solid solution. In the toxin molecule Ehrlich describes a *haptophore* group, through the chemical behavior of which he attempts to describe its peculiar action. In order to do so satisfactorily he assumes also a *toxophore* group, which can be isolated under certain conditions in its action from the haptophore group. Thus one acts perhaps under the influence of cold and the other of heat. Certain time differences are also noted. Certain *receptors* or lateral binding chains of molecules are called in by Ehrlich to further elucidate some of the problems. These receptor groups exist naturally in some tissues and are absent in others and the phenomenon of natural immunity was perhaps to be explained by the absence of this group of receptors. Antitoxins are held to be these protoplasmic receptors and their peculiar property of neutralizing the action of the toxins is due to their power of fixing, and thus rendering chemically inert the haptophore groups in the toxins. Ehrlich believes that the diphtheria toxin, elaborated by Loeffler's bacillus, is made up of two distinct substances, a toxin and a toxon, both of which possessed a similar haptophore group and thus were acted upon and fixed by the antitoxin. Certain other bodies, designated by him as *toxoids*, are also present in diphtheria cultures. These are thought to be non-toxic modification of toxins, capable of fixing antitoxins, and it is by means of these that the phenomena of quantitative variations in toxic power are to be explained. Toxoids as well as toxins may be utilized in the production of antitoxins and for especially susceptible individuals modified antitoxins might be prepared from such toxoids.

Immunity.—Dr. Buchner of Munich had a much less fantastical series of hypotheses to explain the phenomena of "natural resistance," a term preferred by him to natural immunity. He reverted to his older theory of the alexins, which were believed to be secretions formed by living leucocytes. The phenomenon of phagocytosis was partly sufficient only to account for many of the resistance phenomena and in the destruction of bacteria it was not an indispensable factor. This seems to be proven by the alleged fact that bacteria have been destroyed in internal organs, in exudations, without the presence of leucocytes. Immunity was regarded by Buchner as threefold. Antitoxic, brought about by the previous use of certain specific substances, toxins or

modifications of the same which have altered their peculiar toxic properties; bactericide, in which the action of certain bacteria, living or dead, induce the diminished susceptibility and, themolytic, or a condition brought about by the use of definite erythrocytes.

Malarial Parasite.—Dr. Laveran described two varieties of the hematozoon of malaria, *hemammeba malariae,* designated as *parva* and *magna,* according to size. These two forms might be found in the same person in different attacks and are not to be thought of as distinct species, but purely as varieties of the same organism. Laveran inclines to the belief that the flagella of the malarial parasite are sexual in their function, being male elements. He also maintained that while *anopheles* was undoubtedly the host of the parasite and was perhaps the most frequent agent in the dissemination of the disease, nevertheless malaria could be contracted by other means than by the bite of this particular mosquito. His researches on artificial immunity had been, thus far, unfruitful.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held April 3, 1900.

Frederick Peterson, M.D., President.

Thyroidectomy for Graves' Disease.—Dr. B. Farquhar Curtis reported this case and presented the patient who was operated on in November, 1897. There had been symptoms for some time previously and the goiter was of moderate size. The eyes were quite prominent and the pulse ranged from 120 to 150. Primary union followed the operation, there was no interference with the general health, and she improved steadily from that time. The left half of the thyroid was removed. Less than two months after the operation she was able to resume her occupation of bookkeeper, and her pulse gradually became slower. Apparently the cure was permanent.

Resection of Sympathetic for Graves' Disease.—Dr. Curtis also reported this case and presented the patient, a woman of twenty-nine years. She had had three children, and the disease was worse during each pregnancy. The symptoms lasted about four years before operation and were quite marked during the last two years. In December, 1898, there was a moderate exophthalmos, a rather rapid pulse, and some nervousness. In May she developed a paralysis of the left vocal cord, and twelve days later Dr. Curtis operated on her at Bellevue Hospital, removing the cervical sympathetic on both sides, but leaving the goiter untouched. While in the hospital the pulse was at no time above 106. Since the operation the nervousness diminished, and the eyes improved decidedly. The first effect of the operation was a reduction of the size of the gland.

Dr. Theodore Janeway said that when she returned to him last January the thyroid was increased in size, the pulse about 90, aortic and systolic murmurs developed, and she suffered a good deal from headache. Examination of the urine was negative.

Dr. Curtis said that he had performed nine thyroidectomies for this disease, and in none had the operation itself been complicated in any way, not even by hemorrhage. Of the nine cases, six recovered and three died. The first of the fatal cases was that of a woman who was in fair condition at the time of operation, but became stupid immediately thereafter, and developed a temperature of 107° F. before death. This death seemed to be chargeable to thyroid-poisoning rather than to uremia. In the second fatal case the symptoms were quite severe and the exophthalmos was marked. She did not suffer much from shock, but the day following operation she became very restless and the temperature and pulse rose rapidly. She suddenly succumbed, apparently from heart failure. The third fatal case was that of a woman of twenty-three years, apparently in excellent condition, with a moderately large goiter and a good deal of nervousness. She stood the operation well, but thirty hours later developed a very rapid pulse and respiration, together with a high temperature and great nervous excitement. A little albumin was found in the urine. In all three cases there was nothing, from a surgical standpoint, to criticise; hence, he believed the fatal result might be attributed to thyroid-poisoning. He had never seen such symptoms in an ordinary case of thyroidectomy. It was worthy of note that in one of the cases, marked by a pulse varying from 120 to 150, the pulse dropped to 100 before the patient left the operating-table, and since then varied between 90 and 100.

Dr. Graeme M. Hammond said that the results obtained by Dr. Curtis seemed to point very strongly to the majority of these cases being the result of a hyperactivity of the thyroid gland. It was not improbable that some special nervous condition was the underlying cause of this hyperactivity of this gland. He thought one should hesitate before advising thyroidectomy in cases of exophthalmic goiter in view of a mortality of 33 1/3 per cent. It would be interesting to know the effect of the administration of thyroid extract in cases exhibiting these toxic symptoms after operation.

Dr. E. D. Fisher said that he had seen a patient in whom the cervical ganglia had been resected and her general condition had certainly improved. A number of these operations had been reported, and it seemed to be a justifiable procedure. Some operators reported the occurrence of considerable hemorrhage at the operation and explained it by the marked dilatation of the blood-vessels present, supposed to be a part of the effect of the cervical sympathetic. In some of the cases relief followed even removal of one ganglion. On the removal of each ganglion in the case just presented there was noted a very transient dilatation of the pupil on that side.

Dr. W. M. Leszynsky said that the prognosis of Basedow's disease always seemed to him to depend largely upon the financial ability of the patient. It was for this reason that patients of the poorer class found it desirable to submit to operation. He had tried repeatedly, and in vain, to secure the admission of such patients to our city hospitals for a prolonged course of treatment.

Dr. Fisher thought many of these cases did not respond to even the best methods of treatment, and under the most favorable conditions.

Dr. Leszynsky contended that the early resort to proper treatment, an essential feature of which was prolonged rest, would cure very many cases.

Dr. Peterson took the same view as the last speaker. Both operations described by Dr. Curtis seemed to him very serious ones to undertake until safer methods of treatment had been given a fair trial.

Dr. Curtis said in his cases the opinion had been expressed at the time that the poisonous symptoms were the result of the escape of too much thyroid secretion into the system. It was possible that earlier operation would eliminate this danger.

Word-Deafness and Naming Center. — Dr. Graeme M. Hammond, who read this paper, said that Broadbent first brought forward, as a theoretical proposition, this "naming center," but it had not been placed on a more tangible basis until a case had been carefully observed and reported by Mills. The speaker said he had suggested that the cells which were the most highly organized would be the ones which would naturally retain and register the names. If this were the case, the location of the centers in which the names were stored might differ materially in different individuals. Further study, however, led him to think that such a theory was not necessary to a proper understanding of the cases already reported by others, as well as by himself. Dr. Hammond then presented an illustrative case—that of a man who was injured in a fight on May 8, 1899. He was struck on the temple and was able to walk home, but a few hours later had a severe general convulsion and lost the power to name objects. He could talk voluntarily and could say most words except the names of objects and persons. He recognized familiar objects, as evidenced by gestures, but he could not give their names or repeat them after they had been told him. Dr. Seneca D. Powell operated upon the man and found a linear fracture of the temporal bone and a clot which completely covered the superior temporal convolution. At about the junction of the posterior-third with the middle-third was a hole about the diameter of an ordinary lead pencil and fully one inch in depth. He made an excellent recovery from the operation and soon regained the power of naming objects, but the word-deafness had never entirely disappeared. At the present time he found it difficult to pronounce words of three syllables or more.

Dr. Hammond also reported a case in which there was softening of the middle-third of the second temporal convolution. The patient entered the Charity Hospital on January 9, 1900. He was about forty years of age and had a fair education. He was comatose at the time of his admission, but soon recovered his mental condition for the most part. There was no motor weakness and disorders of sensibility were not noted. The special senses appeared to be unimpaired. He was almost completely word-deaf, and was also completely word-blind, and had absolute agraphia. He could not write from dictation or copy simple geometric figures. He was, however, by no means stupid. Had he lived a diagnosis of a lesion of the superior temporal convolution and of the angular gyrus would have been made, and yet, as shown by the autopsy, neither of these regions had been implicated at all. In the first case, loss of power to name objects did not depend primarily upon the lesion. In the second case, the lesion implicated was almost outside of the accepted region for the naming center. In Mills' case word-blindness had been associated with anomia and yet the lesion had been further from the higher visual center than in the second case just reported. The speaker thought the presence of word-blindness or word-deafness, either alone or in combination, only implies that a lesion in any part of the speech area may give rise to various forms of aphasia. It seemed probable that any lesion disturbing any part of the speech area might cause anomia, and hence it could be understood how two such widely-separated lesions as in Mills' case and in his own could produce like results.

Dr. E. D. Fisher suggested as a possible explanation that in the case just reported the lesion was more deeply seated than in Mills' case—not in the cortex proper, but in the fibers leading from it.

Dr. Joseph Fraenkel said that the patient presented seemed to understand the meaning of the words pronounced, the defect seeming to be rather motor than a pure word-deafness. It seemed to him, therefore, that the man had recovered from his aphasic disorder. Concerning the existence of a naming center, the speaker said that he agreed with Dr. Hammond that there was no distinct naming center. He had at present under observation a male syphilitic, about forty years of age, who had been recently exhibiting impaired mental faculties and a spastic paralysis of the right upper extremity. In addition, he was absolutely unable to name an object shown him, but he could define the use of the object. In this case he felt convinced that there was one sufficiently large lesion in the arm center to encroach slightly upon the speech center. A mild interference with the speech area would lead to marked disturbance of the higher and more complex functions associated with speech.

A SIMPLE AND EFFICIENT TREATMENT OF TALIPES CALCANEUS PARALYTICUS IN YOUNG CHILDREN.[1]

BY V. P. GIBNEY, M.D., LL.D.,

OF NEW YORK;

CLINICAL PROFESSOR OF ORTHOPEDIC SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS.

FOR a number of years in my own hands the treatment of calcaneus in young children was unsatisfactory, and my experience with the various mechanical devices had failed to convince me that one could reasonably expect a cure. The difficulty lay in the construction of an apparatus that would keep the foot fully extended at all times, without making such apparatus too cumbersome. The ordinary "reverse catch," which we have all had so much to do with, so frequently got out of order that I rather despaired of securing continuous extension, because time and again this catch would get out of order, the foot-plate would break, or the shoe bend at the sole, and the patient would come in walking on the heel. Even in the hospital where I was enabled to keep the appliance in reasonably good repair, it was exceedingly difficult to maintain continuous extension of the foot.

In thinking over the explanations given for the production of deformity in a paralyzed limb, I was convinced that long-continued position contributed largely to the shortening of a tendon in a paralyzed muscle. For instance: The ham strings would shorten, and even the muscles themselves about the hip would shorten. The writer has witnessed a number of cases in which flexion deformity existed and division of muscles or stretching was necessary before an apparatus for a paralyzed limb could be properly adjusted.

Case I.—In 1895, I had a little patient, eighteen months of age, whose parents wanted to spend the summer in Maine, and although they were supplied with two or three braces, the little fellow was so heavy that he would soon get them out of repair. I determined therefore to put his foot in extreme extension and maintain this position at all hazards; so I resorted to plaster-of-Paris. I explained to the parents fully the length of time which this plaster must be worn, and I provided a wedge-shaped piece of felting so that a shoe could be worn with comfort, thus enabling the patient to get about with a great amount of ease. The child had an attack of poliomyelitis in September, 1894. The lesion was not an extensive one, but there remained a paralysis of the gastrocnemius and of the posterior tibial groups. It was on June 27, 1895, that my first observation was made, and although I provided him with the appliance above named on November 6, 1895, I found that the calcaneus was even more marked, in fact, that the brace had done no good. I proposed an operation for shortening the tendo Achillis, but it was not accepted, and I determined, for the present, at least, to put him in plaster-of-Paris, which I did on November 9th. It remained unchanged until December 7th. The tendo Achillis was perceptibly shorter; there were no excoriations when the plaster was renewed. It was reapplied at once and removed again on January 23d. The tendo Achillis was decidedly shorter and the foot could be brought in dorsoflexion only to 90°. The plaster was renewed on May 2, 1896, and again on June 1st, no excoriations at any time having appeared. At this last date I made a removable cast which he wore to December, 1896.

A note which I made on November 2d reads to the effect that it was impossible to bring the foot in flexion to 90°. The tendo Achillis was not only short but quite strong. I made him an apparatus at this time to correct the valgus, hoping thereby to secure some shortening of the posterior tibial. From this time I had no further trouble with the calcaneus. The apparatus was worn without any great strain, and it was easy to keep it in repair. From January, 1897, to March, 1900, I saw him from time to time, resorting to various measures to improve the posterior tibial, but without much avail. He developed an equino valgus. Even without his apparatus he would walk, and yet the tendo Achillis would remain short. I determined, therefore, to do some tendon-grafting, and on March 30th I made a long incision in front of the ankle, toward the inner side, exposing the tendons of the posterior tibial, anterior tibial, the flexor brevis pollicis and the common extensors. I detached the flexor brevis pollicis from its insertion and some tendons of the common extensors, and passing these ends through the buttonhole in the posterior tibial, just in front of the malleolus, fastened them with fine silk. I then dragged over the larger portion of the common extensor to the inner side and tied these to the posterior tibial with kangaroo tendon. Even under an anesthetic I was unable to stretch the tendo Achillis so that the foot would stand at right angles with the leg. I did not care to divide the tendon, but thought at the next dressing or so I should be able to complete the extension. This proved true, and on April 12th, less than a month after the operation, I succeeded in stretching the tendon so that the foot was brought quite to 90°. It was interesting to note how strong and large

[1] Read before the American Orthopedic Association, Washington, May, 1900.

the tendo Achillis was. The result of the operation, thus far, is very good. The child has now practically a normal foot. He can make flexion and extension without this annoying eversion of the foot. I have no fear whatever of any trouble with the original deformity, *viz.*, calcaneus.

Case II.—A girl, five years of age, came under my observation on January 27, 1898. Her attack of poliomyelitis was in July of that year, but a marked atrophy and the deformity did not begin until some time in October or November. I found the tendo Achillis quite long. The foot and leg were cold, the child as she walked used the heel. I obtained such excellent results in the preceding case that I spent considerable time in explaining to the parents the necessity for the treatment I proposed to adopt. This was the plaster-of-Paris in complete extension and it was continued unremittingly, the plaster being changed every three or four months until the fall of 1899, over a year and a half. It was interesting to note the development of the tendon and even of the calf, in spite of the plaster-of-Paris. There was fully one inch difference at the time. Now there is scarcely half an inch. She is wearing a little ankle-support and has a foot that is just about normal.

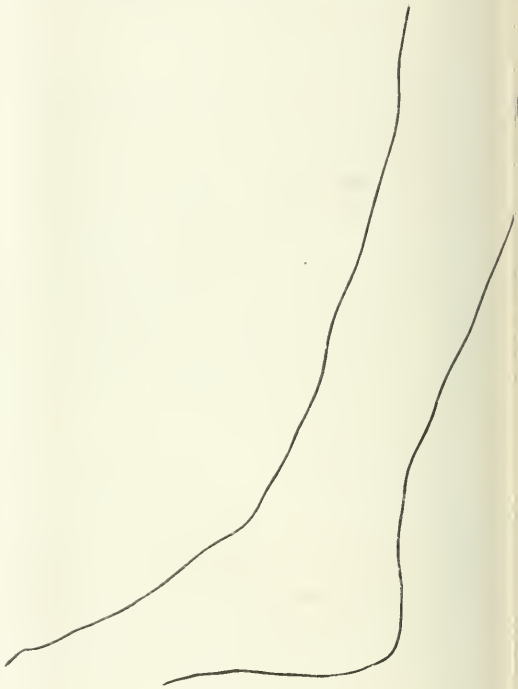
There are still under treatment two unfinished cases, but the result is already apparent, and, from my experience with those just reported, I feel assured that the final results will be equally good.

Case III.—This was a girl, three and a half years of age, from Cleveland, Ohio, whose poliomyelitis occurred when she was fifteen months of age. It was many weeks afterward before she was able to use the limb. When I saw her on March 16, 1899, she walked with a marked calcaneus limp, striking the heel first. The right limb from the anterior superior spinous process measured 17¾ inches, the left 18¼; from the umbilicus, right side, 19¼ inches; left, 20¼; thigh, 6 inches from the anterior superior spinous process, right side, 9¾; left, 10½. Right knee, 8; left, 8½; right calf, 6½; left, 7½. The foot was ½ inch shorter than its fellow and over the instep there was a difference of ¾ of an inch. The outline of the foot in March, 1899, is shown in Figure 1. On February 19, 1900, it was as shown in Figure 2. Figure 1 shows the position in which the foot naturally rested. Figure 2 was the best dorso-flexion I could make without the employment of great force. As she attempted to make dorso-flexion the great toe was drawn in, trigger toe,

FIG. 1.

Before Operation.

FIG. 2.



After Operation.

and she could not quite reach 90°. There was a little tilting of the pelvis, but no spinal curvature. The mother was very incredulous when I proposed the plaster-of-Paris treatment, and it was only after considerable argument that she consented to this treatment. She remained a few days in the city to see that the toes did not swell too much, and it was necessary to apply a second one before I got the toes and ball of the foot properly protected. The mother wrote me in June, but the letter was simply a record of the child's daily life; how well she got about and how little discomfort the plaster caused. I did not see her from March 21, 1899, until August 14th, nearly six months, when I removed the plaster, finding a little excoriation at the base of the toes, dorsal aspect, none elsewhere; the improvement was at least 50 per cent. The comparative measurements showed ½ inch increase in the length of the limb, no increase in the size of the thigh, a loss of ½ inch in the circumference of the calf. The plaster was reapplied, and on February 16, 1900, nearly a year from the beginning of treatment, the tendo Achillis was quite strong and the equinus had entirely disappeared. It was at this time that tracing No. 2 was taken. The thigh had increased a full ¼ of an inch, the calf remaining the same as in August. I decided to put on a third plaster bandage, which she is now wearing. I feel that I shall be able to omit all dressing of this kind during the early summer.

Case IV.—This was a boy, three and a half years of age, who came under my care October 17, 1899, with a marked calcaneus, his poliomyelitis developing in July, 1898. The fever was of sudden onset and it was eight or ten days before a diagnosis was made. The child screamed almost continuously, and it was found at the end of this period that his left leg was paralyzed, his right arm partially so. Two or three months later he began to walk. All at once the right arm recovered, and for the past three months he has been walking on his heel. The right ankle measured 8 inches, the left 7. The quadriceps extensor did not act well, while the thigh itself was 1½ inches smaller than its fellow. I put him under the same course of treatment and the plaster was removed for the first time on February 27, 1900. I found the gastrocnemius muscle very sensitive and it was difficult to extend the tendo Achillis. The position of the foot was excellent. The plaster was at once reapplied, and he is still under treatment.

These four cases are presented in evidence of the efficacy of prolonged and uninterrupted extension of the foot. I have not resorted to the method in the older patients, for the reason that it is difficult to keep plaster-of-Paris on a limb sufficiently long to secure a good position. I have not employed water-glass, nor have I attempted leather splints in these young children. I am now employing a leather splint reinforced by steel in front for an adult and it gives me much pleasure to add to this short paper and report an exceedingly interesting case of metatarsalgia, depending apparently on hysterical equinus, division of tendo Achillis, subsequent elongation of same, with a most persistent equinus resulting; finally relieved by prolonged extension.

Case V.—A lady, thirty-five years of age, came under my care September 29, 1896. She had suffered for a long time with metatarsalgia, and had been under the care of two distinguished surgeons in Philadelphia. At the time I saw her the pain was referred to the distal ends of the second and third metatarsal bones. There was a moderate amount of flatfoot, but the tendo Achillis was short and I could not flex the foot to 90°. There was no pain on pressure between the fourth and fifth metatarsals. I ordered a shoe built on a Spanish last, in order to correct the flatfoot, and I had the heels rather high, so that there would not be any strain on the tendo Achillis. Two months later the shoes were comfortable but there seemed to be too much pressure against the arch of the foot. She, herself, a trained nurse, had long since got the impression that her tendo Achillis was too short, so the latter part of December, 1896, she asked my permission to have a surgeon in a suburban town divide the tendon. I offered to make any suggestions to the surgeon if he so desired. A few days later, in response to a letter from this gentleman, I wrote him, giving in detail the steps of the operation, the subsequent management, etc. I insisted on a great amount of care in the management of the tendon, as I was afraid that she would abuse his treatment and get the tendon too long. On April 14, 1897, she reported herself perfectly free from her metatarsalgia, and gave this history: The operation had been done as instructed, the foot was put up in plaster-of-Paris, but she removed it in a few days "because of the development of gout." A brace was employed at this time and worn not very regularly. I found the tendon quite small. It was too long and there was a transverse depression into which one could put the finger, just near the point where the tendon joins the muscle. There was increased atrophy of the limb since the operation. I naturally felt that I could not be responsible for this condition, and advised that she keep the foot extended as much as possible and prevent dorsoflexion at any time. I saw very little of her during that year. On April 12, 1898, she told me that she had been very weak since the operation, and I found a very marked calcaneus; indeed, there was scarcely any of the tendon left. She had a good deal of spasm of the flexors of the toes and finally I urged the plaster-of-Paris with foot extended; in the meantime, however, I had a wedge-shaped piece of cork inserted in the heel of the shoe. Shortly afterward I applied a water-glass bandage, and while the water-glass was setting under the plaster, she became quite hysterical and the bandage had to be removed. On July 19th and 23d these were repeated with the same results, that is, great pain and objection to wearing any hard splint. It required a great

amount of persuasion to induce her to continue treatment of this kind. In August, 1898, there was evidence of increased growth of the tendon. I was obliged to employ a brace at this time, but under protest. On February 8, 1899, there was still a marked calcaneus, but she managed to get about fairly well with the apparatus. The toes annoyed her a good deal and on April 21, 1899, under ether, I divided the tendons of the flexor brevis pollicis and the common extensors, subcutaneously, and secured complete extension of the toes; in fact, brought them into flexion. The foot was likewise extended and plaster-of-Paris employed from the tips of the toes to the upper part of the calf, avoiding all pressure over the tendo Achillis. She was in hospital at this time and I could command better discipline. Within two or three weeks, however, she developed another hysterical attack. Her stomach "gave out" and I was obliged to resort to water-glass again, which she wore until August, 1899. Then I took a cast of her foot and had a leather splint made, reinforced well in front, with foot in pretty sharp extension. So the case progressed. My last observation was on March 23d of present year, and I found at this time a pretty strong tendo Achillis. In fact, it was just about normal. This depression had disappeared, and she was able to flex and extend the thigh with great ease. I saw her at this time in conjunction with Dr. Joseph Collins, who injected strychnine hypodermically into the calf muscles, as a remedy for her neurasthenia. The result on the whole, therefore, is excellent. It has been a most exasperating case in many respects, yet by persisting in the treatment I am able to report so favorably.

In conclusion, I may say that almost any appliance which is worn night and day, the management of which is taken completely out of the patient's hands, should bring about like results. My fondness for plaster-of-Paris has prejudiced me in its favor, and yet I can readily see how any other dressing which will meet the indications could be employed with equal advantage.

IN WHAT RELATION DOES OCCUPATION STAND TO TUBERCULOSIS?

By W. FREUDENTHAL, M.D.,
OF NEW YORK.

In order to answer the above question, we have to examine statistics, a task undertaken by many persons before me. I am aware that statistics as a rule have only a certain value, and even those that are the most thorough and exact are not such that we can draw absolutely correct mathematical conclusions from them. Especially the publications of statistics regarding tuberculosis number many hundreds and I do not intend to mention them here. Some of them will be discussed later on. It is noticeable, however, that in former years great stress was laid upon nutrition as an etiological factor, but it is difficult to say how far insufficient nutrition has to do with tuberculosis. Still I am inclined for many reasons to believe that in the etiology of tuberculosis poor nutrition has little to do and is perhaps only one of a great many of the causes. One important reason is that we see quite a number of well-fed and well-nourished individuals suddenly show signs of tuberculosis. Further, it has been noticed that in people who have had a hereditary tendency tuberculosis appeared in spite of the fact that they were constantly fed with a great deal of meat and other nourishing substances.

On the other hand it cannot be denied that people with limited and very small incomes—as has been shown by Gebhard—are much more prone to tuberculosis than those of the wealthier classes. Gebhard has studied this question thoroughly and comes to the conclusion that his results were always the same, *viz.*, the lower the average yearly income the higher the rate of tuberculosis; and the higher the average income, the lower the mortality of this disease.

Very similar investigations have been made in Hamburg, and it was found that the mortality of tuberculosis was as follows: Among one thousand taxpayers with an income of more than 3500 marks, 1.07; with an income of 2000 to 3500 marks, 2.01; with an income of 1200 to 2000 marks, 2.64; with an income of 900 to 1200 marks, 3.93. We see, therefore, that here, too, mortality keeps step with the reduction of the income.

That there are many other factors which play an important rôle here is undoubted. Thus the greater density of the population in the poorer districts and with this the greater possibility of infection have been discussed thoroughly enough in this country.

More important, however, than anything else is the occupation of the individual. While I am aware that a great many investigations have been made in this direction, and by competent observers, we have to admit that the results contradict themselves very frequently and cannot be utilized for accurate statistics. For this and many other reasons I have investigated the last 1576 cases of tuberculosis treated at the Montefiore Home in New York, *i. e.*, all the tuberculous patients during the past ten years. Out of the 1576 cases there were 1152 males and 424 females, ranging in age from five to seventy-two years. Before giving you the exact dates of my investigations, I must remark that the number of female patients (424) is too small and the exact occupation of most of them is too uncertain to allow any approximate conclusions. Thus, for example, we only know that by far the greater majority of the married women (241) gave their occupation as housewives. This might mean a great deal as to our question, or nothing. The exact data not being obtainable we shall omit them in deducing our conclusions. Still you will allow me to give you all the statistics, including those of the females also, which latter might per-

haps be used for some reference in the future.

Males.—The number of males was 1152; these ranging in age from five to seventy-two years; of these 670 were married and 463 were single.

Occupations.—These were as follows: Tailors, 183; operators, 99; peddlers, 96; clerks, 54; pressers, 52; cigarmakers, 46; shoemakers, 30; cloakmakers, 30; painters, 27; furriers, 20; shirtmakers, 18; laborers, 12; capmakers, 13; cutters, 12; salesmen, 24; printers, 12; waiters, 11; tinsmiths, 11; agents, 13; school-boys, 10; bookkeepers, 10; merchants, 18, butchers, 9; barkeepers, 8; watchmakers, 8; carpenters, 8; bakers, 8; musicians, 7; machinists, 7; cooks, 7; drivers, 6; buttonhole makers, 6; paper box makers, 5; nurses, 5; photographers, 5; teachers, 6; conductors, 5; stand-keepers, 5; plush-case makers, 4; porters, 4; frame makers, 4; glassblowers, 4; book binders, 4; barbers, 4; cigarette makers, 4; workers on brass, 3; druggists, 3; locksmiths, 3; store-keepers, 3; packers, 3; spinners, 3; pocket-book makers, 3; pearl button makers, 3; necktie makers, 3; weavers, 3; rubber goods makers, 3; dressers, 2; gardeners, 2; trunk makers, 2; brush makers, 2; glass cutters, 2; collectors, 2; compositors, 2; housekeepers, 2; hallboys, 2; workers on passementeries, 2; bookkeepers, 2; typesetters, 2; trimmers, 2; hotelkeepers, 2; spongers, 1; brushers, 1; glovemakers, 1; workers on silverware, 1; gasfitters, 1; overgaiters, 1; real estate business, 1; canvassers, 1; makers of fancy cases, 1; basketmakers, 1; bandagists, 1; gummakers, 1; papermakers, 1; springmakers, 1; artists, 1; diamond workers, 1; diamond polishers, 1; worker on novelties, 1; fishermen, 1; caterers, 1; superintendents, 1; booksellers, 1; coppersmiths, 1; cordmakers, 1; reporters, 1; signers 1; finishers, 1; founders, 1; upholsterers, 1; drummers, 1; shipping-clerk, 1; rag assorters, 1; messenger boys, 1; newspapers 7; paper hangers, 1; tanners, 1; keeper of baths, 1; telegraph operators, 1; auctioneers, 1; ironers, 1; bottlers, 1; hatmakers, 1; watchmen, 1; janitors, 1; workers in lead factories, 1; jewelers, 4; instrument makers, 1; blacksmiths, 1; electricians, 1.

Those not accounted for have no occupation indicated.

Females.—The total number of females was 424; these ranged in age from six to sixty-six years. Of this number 241 were married and 134 were single.

Occupations.—These were as follows: Servants, 27; housewives, 19; tailoring, 18; seamstresses, 9; necktiemakers, 7; salesladies, 6; shirtmakers, 6; schoolgirls, 5; operators, 5; cigarmakers, 4; workers on white goods, 3; hatmakers, 2; cooks, 2; finishers, 2; midwives, 1; flowermakers, 1; feathermakers, 1; trimmers, 1; workers on furs, 1; cigarettemakers, 1; dressers, 1; milliners, 1.

Those not accounted for have no occupation indicated.

There is one striking fact in looking over the above statistics, *viz.*, the extraordinary large number of tailors and those with similar occupations who were suffering from tuberculosis. Of course we have to take into consideration that the bulk of the inmates of the Montefiore Home is made up of Polish and Russian Jewish immigrants, who as a rule land in this country with very little or no means. They learn that trade which will yield them some income in the shortest possible time, *viz.*, tailoring, "operating," etc. To this trade they adhere until they get sick. You all know better than I am able to describe it the dreadful condition of the sweatshops in which these people are forced to work from ten to sixteen hours a day, and that in the worst imaginable atmosphere. I will only add that when these modern slaves come home from work they do not get into better surroundings. The atmosphere of their homes—if you can call such dungeons homes—is, if possible, worse than in the sweatshops. A small room inhabited by six to eight persons and used as kitchen, dining-room, bedroom, etc., with no direct light, almost entirely dark all day long in the rear of a tenement-house, is nothing unusual in the metropolis of the United States. The liberty of building such pestholes for the sole benefit of the owners of these houses has become one of the greatest crimes in New York City which, as yet, is not punishable by law. You will not be surprised, therefore, at the great number of such people who acquire consumption. If I only class the tailors, operators, pressers, cloakmakers, capmakers and cutters in one group, as they are the ones most subject to the sweatshop slavery, we have among 1152 male tuberculous patients not less than 389 of this class. In other words, more than one-third of all consumptives were tailors and workers in allied trades. If in general one-seventh of all deaths occur from tuberculosis, how is it that we have here more than one-third of all tuberculosis cases?

It is a well-known fact that tailors as a rule are more predisposed to tuberculosis than those in other vocations. This may be due to their bent position, lack of proper exercise and other causes. Even in the armies, as for example the German army, where more attention is paid to hygienic measures, the mortality-rate from tuberculosis of those men who do the tailoring work is, according to Schjerning, much higher than those who do active service. Still there is nowhere such an abnormal proportion as we find among the tailors in New York City. In studying this question we naturally have to ask for the reasons of such increased infection. The habitus, lack of exercise, bad ventilation, overwork, undernutrition and lack of all hygienic precautions, all tend to produce that condition *par excellence* for which Bouchardat has invented the genial name of "physiological misery." Perhaps this will lead us to understand the earlier periods of the tuberculous disease. I have expressed my opinion elsewhere that consumption is primarily a trophoneurotic affection of both a general and local nature. It is only later that an

invasion of the tubercle bacilli takes place. Some believe that the primary seat of this neurotic affection lies in the medulla oblongata with special implication of the vagus nuclei; Thomas J. Mays and others are convinced that phthisis is alone due to an affection of the vagi. This latter assertion cannot be perfectly correct, for only the trophic fibers are affected, while the pulmonary branches of the vagus carry motor, sensory and centripetal and centrifugal vasomotor fibers also. Strebel, for example, does not believe, and I agree with him there, that the trophic fibers of the vagus alone are affected, but that the nerve takes part in the general trophic insufficiency in the consumptive; that secondarily, perhaps, degenerations in the vagus and medulla may be seen is very plausible.

In this connection you will allow me to quote from an excellent article written some years ago by Dr. Solomon Solis-Cohen[1] of Philadelphia. His standpoint is somewhat similar to mine. He says: "That condition which makes the human tissues a receptive soil, a favorable culture medium for the tubercle bacillus; that condition which of old was called diathesis and now susceptibility, is itself a disease, a departure from the normal; and I believe it to be the most important element in the morbid complexus termed tuberculosis." This condition he calls with Jaccoud, hypotrophy, *i. e.*, defective nutrition. While the term hypotrophy characterizes quite well certain conditions of the prebacillary stage, it does not cover the whole ground. There must be present some *humoral* defect, or insufficiency, in the tissues of the organism, which as yet has not been demonstrated in the blood circulation but of which I have no doubt we shall hear more in the future. Thus far nothing has been published that could give us any satisfactory evidence about this lack of good circulation, but nevertheless it does exist. When such a person with trophic and circulatory insufficiency, as I might call it, develops in any part of the body favorable conditions for the development of microbes, we are sure that tubercle bacilli will flourish here and a local and afterward a general infection is bound to take place. I have demonstrated this for the retropharynx and believe that in many cases the primary infection takes place there, a belief that was confirmed by prominent men here and abroad, as for example, Prof. Chiari of Vienna, Prof. Seifert of Würzburg, and many others. Dr. Solis-Cohen is not of the opinion that the tubercle bacillus of itself originates the disease, "while it is perhaps the most important of several microbes that influence the progress of the lesions in various forms of the disease." This idea of Dr. Cohen's which seems to be spreading here and abroad seems not to be perfectly correct. While I have always admitted that there must be something else besides the tubercle bacilli to produce the disease, I have shown in the above experiments that tuberculosis does develop when once the tubercle bacilli find a fertile soil to thrive in, be this primarily in the retropharynx or at any other part, which was temporarily the *locus minimae resistantiae*.

Let us apply this to our tailors and we see the following: For years and years numbers of these men come to my throat department for treatment. Their complaints are so uniform and so characteristic that I need not ask them for their occupation; I know they are tailors. They all have a more or less dry, atrophic condition of the mucous membranes in the nose and throat, and they all have a postnasal catarrh. That this catarrh with its stagnating, adhesive, dried secretion which lies at the retropharynx for weeks, is the best culture medium for the tubercle bacillus I have shown elsewhere. I will only repeat here that I have seen tuberculous ulcerations develop at this place, thus proving, as I believe, that there was an open door for the invasion, settlement and development of the tubercle bacilli. How general tuberculosis develops from this spot and spreads to the lungs, etc., as well as for other details, I have to refer to my article.[1]

On the other hand, I have examined 75 consumptives at random. Of these 37 did not complain at all of their throat or nose and 38 did, *i. e.*, about half on each side. Of the 37 patients who did not complain not less than 23 showed marked abnormalities in their nasal passages and in only 14 were there no marked changes at all. Although these examinations are not extensive, I am sure that they will prove convincingly that consumptives suffer from nose and throat troubles not only as much as but more than other people. Two-thirds of those who did not complain had some kind of affection of the throat or nose, and naturally the others who did complain showed lesions of the parts also.

In conclusion I will say that in this paper I had to limit myself to almost one sort of occupation, but it will readily be seen that this one is only a prototype of many others living under similar conditions, and my general conclusion is in accordance with Flint's, "that occupation has an agency in the etiology of pulmonary tuberculosis, in so far as it is sedentary and involves confinement within doors. If it be said that this conclusion is in accordance with what is already known, I answer, that the correctness of the conclusion is thereby made the more certain."

New York Board of Health and Plague.—Michael C. Murphy, President of the Board of Health of the City of New York, has given out some of the preliminary plans for a new bacterial laboratory for the municipality. It is to be a one-story building, built according to the best models and is to be devoted solely to the investigation of the bacillus of the plague. It is to be situated somewhere near the Willard Parker Hospital.

MULTIPLE TRAUMATIC HEMORRHAGES OF THE LIVER ASSOCIATED WITH MULTIPLE PULMONARY EMBOLI OF LIVER-CELLS AND GIANT CELLS RESEMBLING BONE-MARROW CELLS.[1]

By ALDRED SCOTT WARTHIN, M.D., PH.D.,
OF ANN ARBOR, MICHIGAN;
ASSISTANT PROFESSOR OF PATHOLOGY, UNIVERSITY OF MICHIGAN.

THE microscopical appearances in trauma of the liver have been but rarely the object of pathological investigation, and only within recent years has it been shown that as a result of injuries to this organ its parenchymatous cells may be set free into the blood-stream, and through metastasis lead to the formation of liver-cell emboli in the blood-vessels of the lungs.

Turner in 1884 was the first to observe free liver-cells lying within the hepatic vessels, and to draw an analogy between this occurrence and that of fat-embolism. In 1886 he saw two other cases of a similar condition, and following him Jürgens, v. Recklinghausen, Schmorl, v. Zenker, Pilliet, Prutz, Klebs, Hess, Lubarsch and Flexner have reported observations of the metastasis of liver-cells and the formation of liver-cell emboli in the pulmonary vessels. Retrograde metastasis of these cells into the cerebral and renal veins has been seen by Schmorl and Lubarsch, and the same observers have also seen a paradoxical metastasis of liver-cells in cases of patent foramen ovale. In these the liver-cells were found in the capillaries of the brain, kidneys, and other organs, while emboli of the same cells were found blocking the foramen.

The pathological conditions associated with or leading to this metastasis have been as follows: Traumatic rupture and laceration of the liver, hemorrhage and necrosis of the organ in eclampsia, sepsis, acute yellow atrophy, abscess, gumma, scarlet fever, chorea and delirium tremens. In the cases of traumatism large masses of hepatic tissue have been found plugging the larger branches of the pulmonary arteries. The more severe the injury to the liver the larger and more numerous are the emboli found in the lung. In eclampsia, sepsis, etc., the transported cells are usually single or in small groups. No evidence of proliferation in the cells thus misplaced has been observed. Both observation and experiment show that they undergo an early necrosis.

In intimate association with the development of our knowledge concerning liver-cell embolism has been that of the general theory of parenchymatous cell-metastasis. Emboli of placental cells in the pulmonary capillaries were discovered by Schmorl in 1893 to occur in cases of puerperal eclampsia, and especial significance was attached by him to their presence as having a causal relation to the condition or to some of its important symptoms. It has since been found that these emboli, while frequent, are not constant in this disease, and they have been shown to occur in pregnant women without eclampsia (Lubarsch, Leusden, Kassjanow). Doubt as to the placental origin of these cells has also been raised by Aschoff who found similar cells in many widely-varying conditions.

Almost coincidentally with Schmorl's discovery Lubarsch observed large giant cells in the pulmonary capillaries which he regarded as bone-marrow cells. Similar findings were soon after reported by Aschoff and later by Maximow. Aschoff, however, is in doubt as to the origin of these giant cells. Having found them in two cases of eclampsia he considers the possibility of their identity with the cells described by Schmorl, and since he found the same cells in cases of erysipelas, pneumonia, diphtheria, cholera, carcinoma, leukemia, peritonitis, burns of skin, fractures, etc., he rejects the assumption that they are of placental origin, and considers them as being most probably bone-marrow cells. Lubarsch in reply to Aschoff holds that the cells described by the latter are not identical with the bone-marrow cells observed by him, nor with the placental cells of Schmorl. The questions raised by Aschoff remain at the present time unsettled, and the origin of these cells has not yet been definitely proved.

Pulmonary emboli of kidney-cells have also been described by Schmorl, but these have been shown to be undoubted artefacts. Further, portions of bone and medullary substance have been found in the pulmonary capillaries, and Welch has noted the presence of "splenic" giant cells in the liver-capillaries. Our present knowledge of parenchymatous cell-metastasis is, therefore, limited to that of hepatic tissue, bone-tissues, and certain large poly- or mononuclear giant cells which are thought to be either placental cells, splenic or bone-marrow cells.

The case which I report in this paper is of interest as being an addition to the small series of cases of liver-cell embolism already described, and also because of the occurrence of multiple pulmonary emboli of giant cells similar to those observed by Schmorl, Lubarsch and Aschoff. The case is from the surgical clinic of Dr. Nancrede.

Wm. G., aged twenty-four years, an unmarried farm-hand living in the country near Ann Arbor, was brought to the University Hospital on the morning of August 18, 1899. He had fallen from a beam in the barn where he had been working, and had alighted upon the upright handle of a pitchfork which had entered his perineum to the left of the anus. The force of the fall had been so great that the handle had been driven upward into the body to a distance of twelve or more inches, "as far as his stomach." The injured man had withdrawn the handle before his condition was discovered.

The patient when brought to the hospital was suffering from shock and his condition was so serious that a diagnosis of severe laceration of the intestines was made and he was at once operated upon by Dr. Nancrede and Dr. Darling. A median incision was made below the umbilicus.

[1] From the Pathological Laboratory of the University of Michigan, Ann Arbor.

Free fecal matter was found in the abdominal cavity. The intestines were very hyperemic and showed five or six distinct bruises in different portions. Two areas were so badly crushed that they appeared almost gangrenous. These were situated in the transverse colon and in the lower portion of the ileum. Blood-clots and fecal matter were found in the pelvis, the pelvic peritoneum was badly torn and bruised and the retroperitoneal tissues infiltrated with blood. In the anterior wall of the rectum, about three inches above the anus, there was an elliptical, ragged tear about three or four inches in circumference. The edges of the wound were covered with fecal matter which also protruded from the opening. Just above the anus a second laceration of the rectum was found, communicating directly with the external wound found in the perineum to the left of the anus. From the position of these wounds it seemed evident that the pitchfork handle passed through the perineum and the rectal wall just above the anus, then obliquely upward across the rectum, through its wall higher up, then through the floor of the pelvis toward the abdominal cavity where, glancing from the brim of the pelvis, it caught the intestines, pushing them violently upward toward the diaphragm. The tissues about the brim of the pelvis were bruised and infiltrated with blood. No marks of injury to the liver or stomach were noticed. The free fecal matter in the peritoneal cavity came entirely from the tear in the rectum.

The injury to the intestine was so widespread and so severe that resection of the damaged loops was considered to be out of the question and an unfavorable prognosis was given. The serous surfaces of the most severely injured portions were approximated, the abdomen washed out, drainage-tube and gauze inserted in the rectal wounds and the abdomen closed. The patient did not recover wholly from the shock, developed a general peritonitis, and died three days later.

The autopsy was conducted by me in the pathological laboratory one hour after death. The following notes are taken in condensed form from the laboratory protocol. Owing to the limited time for making the autopsy the organs were not weighed or measured.

Autopsy-protocol.—Body of rather slender build, well-formed. The musculature is fair and in good condition; there is a moderate amount of panniculus. There is no edema. There are pale hypostatic patches over the back. *Rigor mortis* is present only in the muscles of eyes and jaw. Body-heat is present.

There is a recent laparotomy-wound in the median line below the umbilicus covered with surgical dressings. On removing these a clean wound with adherent edges and stitches in position is seen. On separating edges of wound no pus is found. In the perineum on the left side of the anus there is a ragged, irregular opening containing drainage-tube and gauze. On removing these an opening about three inches in circumference is found, its walls ragged, greenish-gray in color and covered with dark-colored pus.

The abdomen is opened by an incision to the right of the median line. The peritoneal cavity contains a small amount of fluid which is cloudy and hemorrhagic and contains fibrin-masses and a few small bits of fecal matter. The coils of intestines are adherent and covered by a fresh fibrinous exudate which is partly hemorrhagic and partly greenish-gray in color. At the site of the laparotomy-wound the intestines and omentum are adherent to the anterior abdominal wall by strings of fibrin which are easily separated. The omentum is partly rolled up, very much thickened, hyperemic, and adherent to the peritoneum about the edges of the laparotomy-wound.

The serosa of the intestines is swollen, partly red and partly gray in color, and covered with a thick layer of fibrin. Five or six loops of the small intestine and the middle portion of the transverse colon are gangrenous. In two of these gangrenous loops the intestinal wall had been folded in, the serous coats approximated by means of sutures which are still in position. No perforation in the intestinal wall can be found in any portion, although the gangrenous areas are very soft and friable. The mesentery corresponding to these gangrenous loops shows distinct evidence of bruising. It contains numerous extravasations. The serosa of the appendix is slightly swollen and covered with fibrin.

There is a large retroperitoneal extravasation about the brim of the pelvis, most marked at the bifurcation of the abdominal aorta. The wall of this vessel shows a number of small hemorrhages. The floor of the pelvis is covered with a thick layer of fibrin, and shows also a diffuse purulent infiltration. In the wall of the rectum there is a ragged tear, the edges of which are covered with foul greenish-gray pus. Small collections of pus are found in the surrounding tissue.

On opening the intestines, the mucosa of the jejunum, ileum and transverse colon shows dark-green, softened and friable areas corresponding to those already described. In the rectum are two irregular perforations, one just above the anus, communicating with the external wound; the other is in the anterior wall diagonally opposite, three inches higher up. The mucosa of the rectum is deep-red in color, about the perforations it is grayish-green and swollen. The upper tear is elliptical in shape, about four inches in circumference, its edges are ragged and gangrenous. The fat-tissue about the rectum is hemorrhagic and contains small collections of pus.

Stomach.—Along the greater curvature and over the anterior wall there are small scattered hemorrhages. The serosa is thickened. Otherwise it appears normal. The *spleen* is moderately enlarged, soft and hyperemic. The examination of the *adrenals, kidneys,* and *pancreas* is negative.

Liver.—This is much swollen, its edges rounded and the anteroposterior diameter much

increased. The capsule is covered with patches of fibrin. Beneath it there are numerous irregular, dark-red areas, from one to three cms. in diameter. There are also a few yellowish areas of same size and shape which are surrounded by a hemorrhagic zone. On section the cut surface shows many minute lacerations of the liver-substance which are filled with coagulated blood. These are most numerous near the capsule and toward the lower edge of the organ. In almost every instance the hemorrhage arises from the smaller branches of the portal, the walls of which show numerous small tears. Both the hepatic and portal branches contain clots, some of which are quite firm. The larger hemorrhagic areas involve several lobules and extend into the intralobular veins. Immediately around the hemorrhages there is a yellowish, softened zone. The consistency of the organ as a whole is decreased, and the parenchyma is cloudy and of a pale-yellow color. No large rupture of the organ is found, and the external surface shows no marks of direct injury.

The examination of the *genital organs* is negative. The *head* and *spinal cord* were not examined. The *thyroid* is slightly enlarged; otherwise the examination of the neck-organs is negative. The *heart* presents no pathological appearances.

Lungs.—The pleuræ are slightly cloudy and are covered with a fine layer of fibrin. There is a small amount of cloudy fluid in each cavity. Numerous dark-red areas are seen beneath the pleura. These are of firm consistency. On section the parenchyma is very hyperemic and contains many fresh hemorrhagic infarcts. These are for the greater part small in size and are most numerous just beneath the pleura, although occurring throughout the lung. An abundant foamy fluid is obtained on slight pressure. Numerous small, firm thrombi are found in the smaller branches of the pulmonary arteries. These are most numerous in the right lung. There are also firm clots in some of the larger branches of the pulmonary artery and veins.

Microscopical Appearances. — Material was taken from all of the organs and fixed in alcohol and bichloride of mercury. Portions of the lungs, kidneys and liver were also fixed in Flemming's solution, because of the suspicion that fatty embolism might be present. Besides the staining methods commonly used, polychrome methylene blue, Ehrlich's triacid, etc., were employed as specific stains in the study of the giant cells found in the pulmonary capillaries. The interest of the microscopical examination centers about the liver and lung.

Liver.—The sections of the liver show hemorrhages of various sizes. The liver-lobules are torn apart by extravasations which in almost every case can be seen to come from ruptures in the walls of the portal branches. The larger extravasations involve several lobules, and in some cases extend into the central vein, the walls of which are torn. The liver-cells bordering upon the extravasation are necrosed, their nuclei partially or entirely gone, their protoplasm granular and staining deep pink with eosin. In many cases portions of liver-rods lie in the extravasations separated from the remaining portion of the lobule by blood and fibrin-masses. The liver-cells are necrosed, but the outline of the liver-rods is preserved and the nuclei of the endothelium still stain. Single necrosed liver-cells lie also scattered and in small groups throughout the extravasations and in the hepatic vessels. These cells can be told only by their size, irregular outline, and their granular, deeply-staining protoplasm, as their nuclei are entirely gone. Around these necrosed cells are masses of hyaline and fibrogranular fibrin. In the sections stained with Weigert's fibrin-stain all of the fibrin stains violet and can be seen completely surrounding the necrosed cells. Fibrillæ of fibrin are also seen attached to and apparently arising from single dead cells. Desquamated and necrosing endothelial cells are also found in the blood-clots of the extravasations, but may be distinguished from the dead, loosened liver-cells by the fact that the latter differ in size and shape, stain more deeply red and are more granular.

Throughout the blood-clots of the extravasations and also in the hepatic veins there are numerous irregular, faintly-outlined, granular masses staining a faint dull pink with eosin, and possessing a slightly yellowish tint. The majority have no vestiges of nuclei remaining, but in sections stained with alum-carmine faint nuclei may be made out in some of them. They do not stain with Weigert's fibrin-stain. They are undoubtedly dead cells, and as all stages of disintegration exist between these and the recognizable liver-cells it may be safely inferred that they are liver-cells far advanced in necrosis and liquefaction. All of the vessels of the liver are congested, and both portal and hepatic branches contain thrombi in which liver-cells as described are found. No fatty embolism is present. The yellowish areas around the hemorrhages consist of necrosing liver-tissues, and the parenchyma of the organ shows throughout a moderate degree of cloudy swelling.

Lung.—All of the smaller pulmonary arteries contain thrombi which either partially or completely obturate the vessel. In these thrombi are found the same faintly-outlined, granular, eosin-staining masses which are present in the liver-vessels and which in that organ were shown without doubt to be liver-cells. These cells are free or scattered in small groups throughout the fibrin-masses of the thrombi and do not stain with Weigert's fibrin-stain. They cannot be blood-plates, fibrin, necrosing endothelium, or degenerating leucocytes, but from their resemblance to the dead liver-cells found in the hepatic vessels must be necrotic liver-cells. This view is further conclusively proved by the discovery of one small portion of liver-lobule in which the outline of the liver-rods is preserved and the nuclei of the endothelium still stain. I am un-

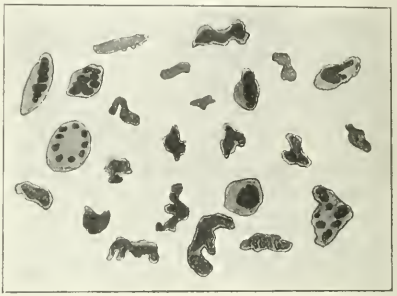
able to find any remains of liver-cells in the lung-capillaries.

A low-power survey of sections taken from any part of the lung shows in the capillaries of the alveolar walls and in the smaller arterioles deeply-staining masses of chromatin, some appearing almost black. They are very irregular in size and shape, but for the greater part are elongated. There is an evident distention or bulging of the capillary at the point where these masses are found. Three to six may be found in some low-power fields. Under the high power these dark masses are seen to be the deeply-staining nuclei of giant cells which are blocking the lumen of the smaller capillaries. These cells are for the greater part mononuclear, but a number of multinuclear ones are found. In the majority of cases no cell-protoplasm can be made out; the cell-nucleus is pushed into the lumen of the capillary and stretched out into a great variety of forms, club, knob-shaped and nodular masses of a coarsely-granular chromatin. In other cases a faintly-staining (with hematoxylin) protoplasm is made out, while in the free giant cells found in the lumina of the large arterioles, which lumina they do not fill, a hyaline plasmodial protoplasm is found. In these conditions the size and shape of these giant cells are easily studied since they are not affected by pressure or crowding. Only a few of these were found, the majority of the giant cells being pushed into the small capillaries.

The further study of these new cells shows them to be very large with a considerable amount of a plasmodial protoplasm resembling that of the syncytial cells of the chorion. This tinges with either hematoxylin or eosin, but more heavily with the former. With alum-carmine it appears light brownish. The cells are either mono- or multinuclear, in the latter case the deeply-staining nuclei are clustered in the central portion of the cell or at the periphery. The size of the chromatin masses blocking the capillaries varies greatly (about 12-16 microns in width and 30-100 microns in length). The free cells in the larger vessels are oval or round, of the size of bone-marrow and placental giant cells, and correspond to these in all respects. The variations in size and form of the capillary emboli are due to the shape of the vessel and the manner in which the cell is crowded into them. The nucleus is drawn and bent according to the windings of the capillary. The fact that the protoplasm cannot be seen in many instances may be explained by the possibility of its having been pushed off from the nucleus as the cell was crowded into the narrow lumen of the capillary.

No granulation can be brought out in the protoplasm by staining with Ehrlich's triacid or Unna's polychrome methylene blue. In this respect the cells resemble the giant cells of the bone-marrow, spleen and placenta. In the sections stained with polychrome methylene blue the body of the nucleus appears as a highly refractive hyaline body on the surface of which lie the granules of deeply-stained chromatin. In a few cells small skeins of chromatin granules project out into the cell-protoplasm. This may be taken as evidence of beginning degeneration, but no other signs of retrograde changes could be found. The nuclei of all the giant cells found are stained very deeply, and no fragmentation or diffusion of the chromatin could be found. No evidences of coagulation processes in association with these cells were found.

Fig. 1.



Forms of giant cells found in the pulmonary vessels. The large cells, showing definite cell-body, are from the small arterioles; the irregular nuclear forms with little or no protoplasm are from the capillaries. Leitz Obj. 7, No. 2. Eyepiece. Camera-lucida drawing. Reduced to two-thirds.

In addition to these changes the lungs showed extreme congestion and edema, and small hemorrhagic infarcts in great number. There were also numerous areas of beginning bronchopneumonia.

The microscopical examination of the other organs showed a universal congestion. No giant cells were found elsewhere, although especial search was made for them in the spleen, liver and kidneys. In the material fixed in Flemming's solution no fatty embolism was found and no evidence of cell-division in the giant cells just described.

At the time of discovery of these giant cells I was struck with the resemblance between them and the cells which had been pointed out to me as placental cells in the lung-capillaries while working in Schmorl's laboratory in Dresden two years ago. Fortunately, in addition to mounted specimens of eclampsia brought from that laboratory containing pulmonary emboli of giant cells which had been demonstrated to me as placental cells, I had brought back a number of paraffin-blocks from two cases of eclampsia which were said to contain these emboli in large numbers. On comparing the sections of the lungs from these cases of eclampsia with those from the case just described, I am unable to make out any difference between the "placental cells" and the giant cells found in my case. Dr.

Dock, to whom I have shown the specimens, agrees with me as to the similarity of the cells found in the two conditions. I have further been unable by means of any special staining, glycogen-test, etc., to make any differential diagnosis between them. The multinuclear cells are more abundant in the eclampsia cases, but no structural differences exist between them and those just described.

The giant cells in my case are *not* placental cells, and they cannot be distinguished from the cells in cases of eclampsia which have been called placental cells; therefore, the doubt naturally arises as to the true source of the cells found in the eclampsia cases. Are they not the same cells as those found by Aschoff, Lubarsch and myself, and have they not the same source of origin? I am able not only to confirm Aschoff's doubt as to the placental origin of these cells, but to refute the criticism of Lubarsch that the cells seen by Aschoff were not similar to those found by Schmorl in eclampsia. The description and illustrations given by Aschoff coincide perfectly with some of the appearances found in my case; and Schmorl's descriptions of the placental cells and Lubarsch's of the bone-marrow cells likewise apply to cells found in this case. Further the cells in specimens of eclampsia from Schmorl's laboratory are so similar that no differential diagnosis can be made between them. Likewise the giant cells found by Leusden in the lung-capillaries in two cases of eclampsia and in two cases of pregnancy without eclampsia correspond to these.

While I am far from denying the possibility of the cells in the eclampsia cases being placental cells and while I am willing to concede that they are, I am in a position to affirm that we have as yet no means of distinguishing them from the giant cells found in the lung capillaries in other conditions in which no placental cells can exist, and that the diagnosis of placental-cell emboli rests at present upon no certain basis. Where villi or portions of villi or decidua pass into the circulation there can, of course, be no doubt as to the origin, but in the case of single giant cells there are no peculiarities of size, form, nucleus or staining that will differentiate placental cells and the other giant cells found in the lung capillaries. The descriptions of Schmorl, Lubarsch, Leusden, Kassjanow and Maximow, respectively, may be applied to cells found in my case.

That the periplacental giant cells may be set free into the circulation by means of direct force exerted upon the uterus (kneading, etc.) Maximow has shown by many experiments made upon pregnant rabbits. In animals whose pregnancy ran a normal course he was unable to find such placental-cell emboli. In the cases where the uterus was subjected to direct injury he found that the placental-cell emboli were not the plasmodial cells of the syncytium, but only the periplacental giant cells and the glycogen-cells of the decidua were set free into the blood-stream and carried to the lungs. There is no reason to doubt the possibility of such an occurrence in the human subject, but the question arises as to the possibility of identification of these cells after their metastasis into the lung-capillaries. If the cells in the two cases of eclampsia which I have studied are decidual cells, then I must hold that this possibility is very slight or with the present technical methods does not exist. It is, of course, possible that these cases of eclampsia are not typical ones and that the cells are not characteristic, but I am unable to find in the various descriptions of the placental-cell emboli any points which will differentiate these from the cells found in my case. Further, the study of sections of the placenta and uterus-wall containing numerous periplacental giant cells shows that many of these resemble the giant cells in my case, and I must confess my inability to distinguish between them. They have no peculiarities of morphology, and the glycogen-test is too unreliable to be used as a differential point.

The question of placental-cell embolism has at the present time about the following status. Schmorl holds that the metastasis of placental cells into the pulmonary vessels occurs only in eclampsia and bears a direct etiological relation to this condition. According to his view the presence of the placental cells in the capillaries of the lung leads to extensive coagulation and thrombosis which he regards as being the direct cause of the more striking phenomena of eclampsia. The constant presence of placental-cell emboli in eclampsia is confirmed by Lubarsch, who found them also in a case of chorea gravidarum without eclampsia; therefore, he holds that these emboli are not the cause but the result of the convulsions of eclampsia. Lubarsch further combats Schmorl's theory by the statement that liver-cell emboli lead to much more extensive thrombosis of the pulmonary capillaries than those of placental cells, but that the former is unaccompanied by eclampsia-like phenomena. Leusden found placental-cell emboli in two cases of eclampsia and also in a case of phthisis dying a few days after delivery and in a case of puerperal sepsis in which death occurred eight days after delivery, both of the latter having no eclamptic symptoms. He therefore holds that placental-cell metastasis is accidental and irrelevant and occurs in puerperal conditions other than eclampsia and will probably be found in normal cases of pregnancy. His lack of material prevented his confirming this hypothesis.

In 1896 Kassjanow published the results of numerous investigations upon the lungs of women dying an accidental death during pregnancy and the puerperium, but who had not suffered from eclampsia. In all cases he found in the pulmonary capillaries emboli of multinuclear giant cells resembling those of the syncytium and corresponding in all respects to the cells described by Schmorl; and he therefore

came to the conclusion that placental-cell embolism is a physiological process and may be found in every pregnancy.

In 1898 Maximow published an account of experiments made upon animals in order to determine if the metastasis of placental cells was a physiological or pathological process. As a result of the thorough examination of the lungs taken from forty rabbits killed in different stages of pregnancy he found no placental cells in the blood or in the pulmonary vessels. In animals in the latter half of pregnancy where direct force was exerted upon the uterus just before the animal was killed, he found periplacental or decidual giant cells in the lung-capillaries, but only in one case a single cell which he thought might be a syncytial cell. In the early stages of pregnancy such embolism was not produced, and he explains this by the fact that the periplacental cells do not exist at that time. In the lungs of normal rabbits, male and female, pregnant and non-pregnant, he also found giant cells which he says have no resemblance to the placental cells; but unfortunately he does not point out the differences between them, and calls them bone-marrow cells without giving any adequate differential diagnosis. From his experiments he concludes that placental-cell embolism is not physiological in the rabbit but may be produced by direct injury to the uterus and its contents, and that the cells set free are not the syncytial cells, as claimed by Schmorl to form the emboli in the human subject, but are the periplacental cells and the glycogen-cells from the decidua.

It will be seen from the above that the status of placental-cell embolism is still very uncertain and that the questions concerning the origin and significance of the process remain yet to be settled. The study of the small amount of literature upon the subject shows that even among these original investigators there is a confusion as to the exact nature of the placental cell. For example, Schmorl describes a case of placental-cell embolism in a pregnant rabbit dying suddenly with symptoms of eclampsia. Maximow advances the proposition that the giant cells seen in this case were not placental cells but bone-marrow cells. Certainly if any one was qualified to distinguish between placental and bone-marrow cells it might be supposed to be Schmorl. Further, Maximow claims that the cells seen by Leusden in his cases of phthisis and puerperal sepsis are not placental cells but bone-marrow cells similar to those seen by Aschoff, but he accepts Leusden's statement that the emboli found in his two cases of eclampsia are composed of placental cells. According to the description given by Leusden the cells in all four cases are the same. As stated in the introduction to this paper, Aschoff who found giant cells of the same kind in eclampsia and in many widely-varying conditions concludes that they are all of bone-marrow origin, while Lubarsch, the original investigator of bone-marrow-cell embolism, claims that Aschoff's cells are not the bone-marrow cells seen by him and that they differ from the placental-cells of Schmorl. He makes this statement, however, without the support of any differential diagnosis.

We must, therefore, conclude that the variety of giant cells found as emboli in the lung-capillaries in different conditions is sufficiently great to cause confusion, and that these various kinds have not yet been so differentiated and described that their identification rests upon a secure basis.

An examination of the lung-sections taken from the last twenty-five autopsies made in this laboratory shows the presence of pulmonary emboli of giant cells in four cases. These are: (1) Fatal anemia (epistaxis); (2) leukemia with acute miliary tuberculosis; (3) pernicious anemia with melanoderma and vitiligo; (4) splenic anemia (splenectomy).

In the first case the giant cells were found in the lungs, liver, spleen, kidneys and lymph-glands. In the second case they occurred in the capillaries of the lungs and kidneys; in the case of pernicious anemia in the lungs and spleen. In the fourth case the spleen was removed three days before death and portions of the organ were taken at the time of the operation for microscopical examination. These show the presence in the blood-spaces of the pulp of many multinuclear and mononuclear giant cells. Sections of the lung and liver prepared from material taken at the autopsy three days after the splenectomy showed numerous capillary emboli of giant cells similar to those found in the spleen. While the giant cells in these four cases have not been as thoroughly studied as in the case of rupture of the liver, yet in all respects with the ordinary stains they appear to be identical with those found in that case and in the eclampsia specimens obtained from Schmorl's laboratory. From their morphological appearances it would be impossible to ascribe to them a different origin.

The question then arises as to the origin of these cells. In none of my cases can they be placental cells, and the bone-marrow, spleen or lymphatic-glands must be taken as the most probable source from which the metastasis arises. Lubarsch came to the conclusion that the giant cells found by him in the lung-capillaries in a case of resection of the hip-joint and in tuberculosis osteomyelitis were of bone-marrow origin; likewise Aschoff excluded other sources of origin for the giant cells observed by him in so many widely-varying affections. This view was also supported by Arnold. Finally, Maximow showed by experiments upon animals that not only single bone-marrow cells, but also portions of the marrow and osseous tissue could be set free by trauma and carried to the lungs. Lubarsch explained the metastasis in his cases by the setting-free of the cells from the marrow-matrix by the trauma caused by operations and also through destructive inflammations of the

bone and bone-marrow. Aschoff came to the conclusion that in his cases the metastasis was due, not to the effects of direct mechanical injury to the bones or to disturbances of blood-pressure, but to chemotaxis brought about by the appearance in the blood of substances causing an emigration of the giant cells from the marrow into the blood-stream. Since he found the giant cells in the pulmonary capillaries in a healthy individual dying suddenly from accidental causes, he came further to the opinion that there may be a physiological leucocytosis of the marrow-cells into the blood.

Arnold confirmed the metastasis of the bone-marrow cells as a result of injury to the bones, but found that it also took place in other conditions where mechanical force played no part, as in artificial dyspnea. He was led to believe that an emigration of these cells took place under certain conditions in which the cells may play the rôle of phagocytes. Maximow's experiments with animals were carried out for the definite purpose of settling the question as to the pathological or physiological nature of the metastasis of the giant cells of the marrow. He arrived at the conclusion that after direct injury to the bones both normal and degenerating bone-marrow giant cells appeared in the circulation, the latter in much greater numbers. He considered the absence of the cell-protoplasm from the nuclei of the giant cells found in the lung-capillaries as an evidence of degeneration, and not, as Aschoff thought, to be due to the slipping-off of the protoplasm as the cell was crowded into the narrow capillary. He further claims that normal giant cells of the marrow are never found in the lung capillaries of animals in whom no direct injury to the bone-marrow is produced, that in these cases only the degenerated forms appear, since these isolate themselves from the tissue of the marrow and pass into the marrow-capillaries whence they are carried out into the general circulation. Maximow found also that the number of these degenerating giant cells in the bone-marrow was greatly increased in the marrow of pregnant rabbits, and for this reason he explains the more frequent occurrence of their metastasis into the lungs of pregnant animals. Lubarsch in reply to Maximow affirms that marrow-cells may pass into the circulation without injury to the marrow; and that in all cases of liver-cell or placental-cell embolism there is a secondary embolism of marrow giant cells which greatly increases the difficulty of differential diagnosis. The differential points he does not give.

I cannot accept Maximow's conclusions in so far as the appearances in the human body are concerned. In all of my cases giant cells showing a well-preserved cell-body were found, and the nuclei of these cells showed the same staining properties as did those of the cells possessing no protoplasmic cell-body. No giant cells showing any advanced stage of degeneration or necrosis were found though careful search was made for them. Only in a few cells were small skeins of chromatin found projecting into the cell-protoplasm from the main body of the nucleus. In all of the cells the nuclei stain very deeply and uniformly and this with their size makes them very easily discoverable in a low-power examination.

That the cells in all of the cases were circulating in the blood at the time of death is shown by their presence in the blood in the larger vessels, the lumina of which they do not fill and where they are not entangled in thrombi. Further, the appearance in many of the small capillaries is more suggestive of ameboid movement than of the position which cells would assume if forcibly pushed into a narrow vessel. The irregular, knobbed nuclei are seen in straight capillaries as well as in winding ones; and further, in some of the larger capillaries elongated, budding nuclei are found possessing a distinct cell-body which does not entirely fill the lumen of the capillary. Red blood-cells and leucocytes lie between the capillary wall and the body of the giant cell, the former not showing the alterations of size and form which would result if the giant cell had been forced into the vessel with them. It is possible that such cells may have been dislodged backward by a retrograde current, but in that case it would seem probable that they would assume their original form. Arnold's observations showed that in the marrow the giant cells slowly changed their form and position, and it seems to me very probable that they show the same ameboid powers when in the lung capillaries.

The absence of cells showing any advanced stage of degeneration leads me to the opinion that the metastasis of these giant cells is in all of my cases either an agonal or pre-agonal leucocytosis, and is probably, as suggested by Aschoff and Arnold, chemotactic or phagocytic in its nature. Whether this pre-agonal emigration of the marrow-cells is a part of the pre-agonal leucocytosis observed in many cases I cannot say. In the only case in my possession where a pre-agonal leucocytosis was noted by the clinician (acute miliary tuberculosis) I have not been able to find any giant cells in the lung capillaries.

It is, of course, probable that under certain conditions, pregnancy, etc., the giant cells enter the circulation without any relation to the occurrence of death. From the findings in the cases of splenic anemia and pernicious anemia following epistaxis there is also the possibility that in these cases giant cells resembling bone-marrow cells may have been formed in the lymph-glands, liver or spleen, as well as in the bone-marrow and that they may bear an intimate relation to the regeneration of the red blood-corpuscles. It is my intention to pursue further the study of the giant cells found in these cases with reference to this question.

Summing up the results of the above study of my case and of the literature I arrive at the

following conclusions concerning the emboli of giant cells found in the pulmonary capillaries:

1. Mono- and multinuclear giant cells appear in the pulmonary vessels in a large variety of widely-varying pathological conditions. In some cases they also appear in the capillaries of the liver, spleen and kidneys.

2. The source of these cells may be either the placenta, bone-marrow, spleen, or lymphatic glands, but we have no means of absolutely determining such origin except in the cases where portions of villi or of marrow tissue are also found.

3. It is not possible with present staining methods to differentiate between single giant cells arising from the syncytium, periplacental tissue, bone-marrow, spleen or lymphatic glands.

4. It is probable that in the majority of cases the giant cells found in the lung-capillaries arise from the bone-marrow, and that in some conditions (pregnancy) the metastasis is physiological, while in others it may be of the nature of an agonal or pre-agonal leucocytosis. In other conditions it may be the result of diseased conditions in the bone-marrow itself. The exact significance of the process remains yet to be discovered, but it is probably of far greater importance than that of an accidental occurrence, as it has generally been considered.

From the study of my case it would also appear that the diagnosis of liver-cell emboli in the lungs is very difficult and practically impossible if pieces of liver-tissue showing distinct structure are not present. My material was taken from the body so soon after death that the changes found in the liver-cells can hardly be considered to be post-mortem, yet all of the liver-cells which were found loosened from their normal relations, either in the hepatic or lung-vessels, showed advanced cloudy swelling and necrosis, to such an extent that the free cells showed no characteristics which would differentiate them from other dead parenchymatous cells. It was only the finding of small portions of liver-tissue showing the liver rods and capillaries with endothelial nuclei still staining that led me finally to the diagnosis of liver-cell embolism. As mentioned above the necrosed cells found singly and in groups were regarded as liver-cells only from their general resemblances to the dead and dying liver-cells found in the larger masses. I should not have felt justified in calling them liver-cells had they alone been found.

It is worthy of note that the liver-cells in my case underwent such rapid death. This accords with all of my observations made upon liver-cells, to the effect that necrosis and degeneration quickly follow any disturbance of their normal relations; so it would be expected that transported liver-cells would quickly die, as was shown in this case. Yet Jürgens advanced the hypothesis and Klebs claimed that the free liver-cells in the blood-stream not only are preserved for a long time but that they may undergo a proliferation. The latter asserted that he found young liver-cells in the capillaries of the kidneys and adrenals. Both Schmorl and Lubarsch oppose this view and doubt the accuracy of Klebs' observations. Lubarsch believes that the loosened cells may be preserved for three weeks, as in one of his cases of eclampsia where death took place twenty days after the convulsion he found emboli showing living liver-cells. This does not prove, however, that the liver-cells had been out of their normal relations for this period of time. In other cases where death occurred five to six days after the attack the majority of the liver-cells showed advanced degenerative changes. In animal experiments the cells quickly necrose, and disappear after one day. Such an early death of liver-cells loosened from their normal relations is in accord with our general experience regarding the life-processes of parenchymatous cells, and I consider it to be most probable that in the human body as well as in the rabbit necrosis of such loosened cells follows almost immediately. Proliferation of such damaged cells cannot take place.

The manner of death of the transported liver-cells in my case was that of a cloudy swelling leading to a simple necrosis and liquefaction. Only in the cells of the larger groups where the necrosis was not so complete were small fat droplets present. As the normal cells of the liver contained no fat the process of fatty degeneration in this case is shown to be of a slower nature than the simple necrosis. In those cells dying quickly no fat is formed, but in the slowly dying ones minute fat droplets are formed. That the dead and dying liver-cells are apparently conducive to coagulation and thrombosis is shown by the fact that in all cases they lie in fibrin masses. This confirms the observations of Lubarsch and also bears out his conclusion that neither liver-cell embolism nor thrombosis of the pulmonary capillaries is the cause of the convulsions of eclampsia.

The absence of the fatty embolism in my case is also worthy of remark. Jürgens looked upon the fatty embolism found in eclampsia and delirium tremens as caused by the associated liver-cell embolism, but Schmorl found it in cases where the liver contained no fat. Maximow held it to be associated with marrow-cell metastasis, but it is not present in any one of my five cases where giant-cell emboli are found in the lung-capillaries. It is, therefore, not an essential accompaniment of either form of embolism.

Because of the difficulty in diagnosis of single necrosed liver-cells in the blood-vessels, I think that all cases where the diagnosis was made from such cells alone should be regarded as doubtful. This is especially true when the liver-cells are found in the hepatic vessels. Schmorl, Lubarsch and Leusden have already pointed out the danger of confusion with artefacts. In the cutting and handling of the liver at the autopsy liver-cells are easily displaced into the vessels, and I have many times observed the presence of

free cells in the vessels in sections taken from blocks cut deep in the tissue, and have always regarded these as artefacts. To my mind the guiding points given by Schmorl for the differential diagnosis between such artefacts and true metastasis of liver-cells into the hepatic vessels are not sufficient. The only safe guide is, I think, the presence of distinct liver lesions in which laceration of the liver lobules and rupture of the hepatic vessels occur. That metastasis of liver-cells occurs in the simple degenerative conditions of that organ observed in many cases of eclampsia, sepsis, acute infections, delirium tremens, etc., as reported by Turner, Jürgens, Klebs, Lubarsch, etc., I consider highly doubtful and believe that the cells seen in these cases were most probably artefacts. There can be but little doubt of this in Turner's and Klebs' cases.

Further, it is highly probable that many of the appearances in the pulmonary capillaries diagnosed as liver-cells were in reality bone-marrow cells. This is clearly shown in the descriptions given by Lubarsch. He found many masses of deeply-staining chromatin which he regarded as degenerating liver-cells. His description of these corresponds in all respects to the various appearances presented by the marrow giant cells. The dying liver-cell does not become hyperchromatic to the degree shown in tumor-cells as is thought to be the case by Lubarsch; there is invariably a gradual fading-out of the nucleus or a diffusion of finely-granular chromatin which also gradually loses its staining power. Lubarsch, himself, says that if placental cells are present as is the case in eclampsia, it is wholly impossible to differentiate between such degenerated liver-cells and placental cells. I have seen no appearances which would make me believe that dying liver-cells ever come in the least to resemble the hyperchromatic giant cells of the placenta or bone-marrow, and I am forced to believe that the cells described by Lubarsch were not liver-cells but either one or the other of the two kinds of giant cells. To my mind also Lubarsch's statement bears out my view of the confusion attending the differential diagnosis of these cells. Further, no processes of coagulation are seen about these deeply-staining masses of chromatin as are in every case found about the dying liver-cells; and this, I think, may be taken as evidence that they do not represent degenerating cells.

In cases of traumatic injury to the liver in which death takes place within a few hours the presence in the lung-vessels of definite portions of liver-tissue put the diagnosis above all question. Such cases are those described by Schmorl, v. Zenker and Hess.

In conclusion, the aim of this paper has been to point out the confusion which exists in the recognition of the giant cells found in the pulmonary vessels, and the fact that at present there are no means of differential diagnosis as to whether these cells are of placental, spleen or bone-marrow origin, and that the significance of such metastasis needs to be cleared up by further investigations. It is my intention to pursue further with reference to these questions the study of the four cases mentioned above.

My thanks are due Dr. Schmorl of Dresden for his kindness in giving me access to the eclampsia material while working in his laboratory as volunteer assistant.

Note.—Specimens of the above case were sent to Dr. Schmorl for examination. In reply he states that he cannot with certainty consider the giant cells in the pulmonary capillaries to be identical with placental cells. Dr. Schmorl has further with great kindness written me fully as to his present point of view concerning the differential diagnosis of these cells. In short, this is as follows: *The placental cell must possess a definite protoplasmic body in which numerous nuclei lie isolated without connecting bands of chromatin. In the narrowest pulmonary capillaries these cells cannot be differentiated from other giant cells; therefore, search should be made for them in the larger capillaries and small arterioles.*

As seen from my drawing and from the description given above cells corresponding in every way to these requirements were found in my case, but were very rare in comparison to the number of mononuclear forms.

POST-APOPLECTIC TEMPERATURE AND DISTURBANCES OF THE ALIMENTARY TRACT: THEIR MANAGEMENT.

By HENRY LYLE WINTER, M.D.,

OF NEW YORK;

INSTRUCTOR IN NERVOUS DISEASES IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; ASSOCIATE IN ANTHROPOLOGY AT THE PATHOLOGICAL INSTITUTE OF THE NEW YORK STATE HOSPITALS.

The cerebral lesions included in the term apoplexy, hemorrhage, embolism and thrombosis, may all be followed by variations in temperature and certain disturbances of the alimentary tract. It is after cerebral hemorrhage that such temperature disturbances are most common and of the greatest range of variation. Those apoplexies affecting the motor area of the cerebrum and followed by more or less complete hemiplegia being most frequent and, in the majority of cases, resulting in the greatest implica-

tion of destruction of tissue, have afforded me more opportunity for observing temperature changes and alimentary disturbances than lesions outside of that area. The rare conditions of amnesia of organic origin dependent upon implication of large cortical areas, and the more common, yet still rare, states of aphasia unaccompanied by motor paralysis of the extremities may also be followed by variations in temperature.

It is usual to find immediately following the cerebral hemorrhage, during the coma, if the lesion has been of sufficient severity to produce a comatose condition, a slightly subnormal temperature; usually from 97.5° to 98° F. After the lapse of a longer or shorter interval of time, a period frequently coinciding with the passage of coma and the resumption of the conscious state, a gradual rise of temperature, up to perhaps 101° F. or even higher, develops. At this stage the temperature, taken in the axilla, is frequently from one to two degrees higher on the paralyzed than on the unaffected side. In those patients who progress favorably the temperature gradually subsides (in about twenty-four hours), although the temperature of the affected side usually remains somewhat higher than that of the opposite side for some days. Subsequently the paralyzed side becomes markedly colder than the well side, a condition which is constantly attendant upon the hemiplegic state.

The accident of infection of the cerebral lesion and the establishment of cerebritis or of localized suppurative areas is fortunately rare, occurring only when trauma or other accident has opened a channel for the entrance of bacteria or where an infected embolus is carried to the brain from already existing foci of disease in other parts of the body. In the latter instance the temperature resulting from the already existing disease is accelerated by the cerebral implication.

Where the lesion is a hemorrhage of large size with continuous coma the temperature frequently rises to 103° F., or even higher. In such instances the temperature rise is coincident with extension of the hemorrhage into the lateral ventricle. Such an extension is followed by fatal results, the patient continuing comatose and the temperature rising until death occurs. Thus continued high temperature is ascribed to one or more of these conditions. From my observations I am led to believe that a continued high temperature, at times irregular in its fluctuations, may be dependent entirely upon the absorption of infective material in the alimentary canal. As the temperature is sometimes the only guide to the condition, the possession of an absolutely harmless and rapidly acting therapeutic agent is of great value as an aid to differential diagnosis. We have such an agent in hydrogen dioxide.

Various disturbances of the digestive organs, usually of a fermentative type, dependent upon a lack of tone of the alimentary tract, occur frequently after cerebral apoplexy. These conditions are often slight and at times absent, as far as we may judge. They are distressing, and at times dangerous conditions calling for active interference not uncommonly arise. In those patients in whom no active alimentary disturbance occurs we find almost constantly a condition which may be described as alimentary torpidity.

Heretofore it has been customary to meet the symptoms arising from fermentative changes with, preferably, small doses of calomel. This drug is sometimes contraindicated and its continued exhibition is very apt to result unfortunately. Other intestinal and stomachic disinfectants have been used with varying results, and no one in particular appears to meet the requirements with any constancy.

Hydrogen dioxide does, however, not only take the place of calomel but seems to be much more effective. Its administration, provided it is pure, is attended by no bad results and its action is rapid. It can be repeated as frequently as necessity requires. In addition to its action upon fermentation it appears to have a slightly stimulating effect upon the digestive functions. I believe that it hastens stomachic digestion, but of this I am not certain. It does, however, overcome the conditions which I have described above as alimentary torpidity.

After the administration of hydrogen dioxide in the first case in which I used it, I found that it not only improved the condition of the alimentary tract, but that the temperature subsided. Within five hours the temperature declined from 101° to 100° F. At the time I was under the impression that this was merely a coincidence, but a similar effect in subsequent cases convinced me that the decline was effected by the medication. Subsequently the occurrence of two cases in which the administration of this agent was followed by a rapid decline of the temperature of the paralyzed side with a slower decline of that on the unaffected side, opened up a field of speculation as to the *modus operandi* of hydrogen dioxide on the economy, acting through the intestinal tract, and also the reason for the presence of temperature changes after apoplexy.

In my first patient the lesion was probably an embolism in the left internal capsule, including the arm and leg fibers. The temperature in the right axilla four hours after the "stroke" and one-half hour after the return of consciousness was 100.6° F., and in the left 99.4° F. Hydrogen dioxide was given, one dram repeated every hour. At the expiration of five hours the temperature in the left axilla was 99° F.; in the right, 99.6° F. This showed a decline of 1° F. on the paralyzed side and only .4° F. on the unaffected side.

The second case was one of hemorrhage into the right internal capsule, producing complete left hemiplegia. The loss of consciousness in

this case extended over a period of twelve hours. The temperature remained subnormal for several hours when it began to rise, continuing rapidly up to 102.2° F. in the left axilla and 101° F. in the right. Owing to difficulty in getting the patient to swallow, hydrogen dioxide was not administered until several (about five) hours afterward, about twenty hours after the "stroke." The axillary temperature then was 101.6° F. left, 100.2° F. right. Dram doses of this remedy were then given, repeated every half hour and the patient's pulse watched closely. This was continued for three hours, and during that time the pulse remained practically unchanged. The axillary temperature then was, left 100.4° F., right 99.8° F. It will be observed that in these two cases the temperature was not only reduced, but the reduction was more rapid on the affected side than on the well side. In all of the other cases the temperature was reduced, but always equally.

The effects of the hydrogen dioxide seem to demonstrate positively that the temperature following the apoplectic "stroke" is due in part to the absorption of septic material in the alimentary canal. The two cases in which the temperature on the affected side fell more rapidly than that of the opposite side pointed to the probability of the temperature being due in part at least to vasomotor disturbances. If this were the case and if the hydrogen dioxide had produced any vasomotor effect the conditions could be demonstrated experimentally. Two similar experiments were made at different times upon the same individual. The subject, a healthy man, inserted his arm in the plethysmograph and a reading was taken. Hydrogen dioxide was then administered, but without any change in the position of the recording column of water. The same results followed the second trial.

I conclude, therefore, that the more rapid fall in the temperature of the paralyzed side was not due to any vasomotor effects of the hydrogen dioxide, but to the fact that with the resumption of more nearly normal conditions of the intestinal tract the circulation also became more perfectly adjusted and the heat was more rapidly lost. In other words the fall in temperature was merely just what we should expect with the resumption of general functional activity.

Therapeutically hydrogen dioxide is an agent which acts well in the alimentary disturbance above mentioned. The reduction of temperature is coincident upon the effects of hydrogen dioxide upon the alimentary conditions. It has been my practice to give the drug combined with an equal quantity of chemically pure glycerin.

1 Madison Avenue.

MEDICAL PROGRESS.

Albuminous Food in Disease.—The carefully written article of J. Flesch (*Klin. therap. Woch.*, August 19, 1900) is a valuable addition to the already extensive literature on artificially prepared proteids for the sick-room. The author first shows that all attempts to entirely prevent loss of weight in febrile and cachectic states will ever prove futile since emaciation is a cardinal symptoms of these conditions, caused no less by the anorexia, disturbances of the digestive tract and the sensorium than by the pathological process itself. A fluid diet is always to be preferred, since the temperature of the fluid can be better controlled and since the toxins are more readily thus washed out of the kidneys. The value of milk lies in the fact that it contains all of the three great classes of foodstuffs, the amount of any one of which can be increased to suit special indications. Thus, milk may be made richer in fat by adding cream or by the use of Gaertner's "Fettmilch," which, however, is often not palatable to the patient; the percentage of carbohydrates can be raised by the addition of milk-sugar, and many of the newer albuminous preparations are available for making it more highly nitrogenous. The simplest procedure for the latter purpose would be to boil down the milk or to add an egg, but to both there are objections. The addition of tropon, sanatogen, sanose, eucasin, somatose or nutrose, the author does not recommend, since the organism does not sufficiently utilize them. Moreover, tropon and sanose have the disadvantage of being insoluble and eucasin and nutrose of having a disagreeable taste. Such faults cannot, however, be found with plasmon, an albuminous body obtained from skimmed milk mechanically by the addition of bicarbonate of sodium, for it agrees perfectly with the patients, increases the consistency of the stools and reduces the loss of weight to a minimum. An important point in its administration is to change the vehicle as much as possible, and the fact that plasmon may be given with almost any food readily permits this. In case plasmon should cause constipation, the addition of milk-sugar is to be considered.

Os Magnum and Wrist-Joint Tuberculosis.—D. E. Mundell (*Annals of Surgery*, August, 1900) considers the os magnum, because of its anatomical relations to adjacent bones, being the pivotal, central and main bone of the wrist, with its seven articulations, most likely to receive the effects of traumata to the wrist bones, especially sprains. Tubercle bacilli manifest themselves in bone by a process of rarefaction. Repeated strains on any bone may favor tuberculosis on account of minute foci of inflammation resulting from the "jarring" of the trabeculæ. As the os magnum is so situated as to receive the effects of injuries from three metacarpal bones, as it performs more movements in flexion and extension than the other bones, and as in their movements greater strain is thrown on it than on the other carpal bones, from the numerous ligaments connected with it and resisting such movements, we have in part an explanation of the os

magnum being so often the principal seat of tuberculosis wrist-joint disease.

Pulmonary Tuberculosis.—Of the different preparations of guaiacol C. J. Whalen (*Medicine*, September, 1900) always had most success with the liquid form given in five-minim capsules after each meal, and increased one drop each day until saturation of the patient. At the same time guaiacol is applied externally, sometimes with marked effect on the cough and fever. If the stomach does not tolerate guaiacol, oil of cloves internally and guaiacol externally may be given. Other excellent remedies are iodine, strychnine and arsenic phosphorus, cod-liver oil and the malt liquors. One of the most pleasant and easily assimilated preparations is red bone-marrow. The diet should be nutritious, chiefly meat, milk, eggs, farinaceous food, and butter. Raw eggs may be taken with great advantage even to the number of two dozen a day. Among inhalations, formalin in two- to twenty-five-per-cent. strength, and inhaled for fifteen minutes twice a day is by far the best. Iodine, carbolic acid, creosote, the oils of white pine, cinnamon, and cloves, and eucalyptol and thymol are also of value. There should be moderate exercise without fatigue, and lung gymnastics such as deep breathing, daily cold applications to the chest and vigorous friction. The diarrhea may be controlled by 40 to 100 grains a day of bismuth, or in extreme cases with acetate of lead and opium. The night-sweats succumb to 1/120 to 1/60 grain of atropine at bedtime, or to 1/6 grain of agaricin. Where these fail ten-grain doses of sulfonal or cold sponging may be of benefit. Hemoptysis as a rule requires no treatment. If, however, there is much restlessness and cough morphine may be administered. The blood-pressure may be lessened by recumbency, saline cathartics, diuretics, and counterirritation. If these measures do not sufficiently lower the arterial tension, aconite, one minim every hour, or veratrum viride, or 1/100 grain of nitroglycerin may be of value. The author believes that tuberculin has no curative power, and his results with the intrapleural injection of nitrogen have been disappointing. In many cases a change of climate is advisable, but not when the patient is likely to suffer from homesickness or be denied the comforts of home. Persons with weak constitutions should never be sent to high altitudes, but should be directed to warm, sheltered places; those with strong constitutions do best in a mountain climate, no degree of cold is contraindicated, providing the altitude is suitable for the stage of the disease. In high altitudes the freedom from bacteria lessens the danger of secondary mixed infection, and the rarefaction of the air brings into use a large portion of the lungs which is not used at a lower level.

Typhoid Fever.—C. H. Andersen (*Medicine*, September, 1900) outlines as follows his treatment of eighty-seven typhoid patients at Fortress Monroe. The patients being in tents and the attendants unskilled, cold baths were not attempted, but a lukewarm bath was given each morning. The bowels were regulated by calomel in two-grain doses two or three times a week if necessary. Two ounces of milk was given every two hours and two ounces of water in the intervening hours, 1/60 grain of strychnine nitrate three times a day, and brandy every four hours or oftener according to the pulse; up to eighteen ounces in twenty-four hours. The milk was gradually increased up to five or six ounces every two hours unless undigested milk appeared in the stool. Peptonized milk was substituted in irritable stomachs. In the third week of convalescence soft-boiled eggs, eggs and milk, ice cream, and soft milk-toast were allowed. Where milk was not well borne a proprietary food was used, and this, mixed with hot water, was also especially useful in irritation of the intestines and diarrhea. Among all these cases there were only five relapses. Hemorrhage occurred in seven cases, and five of these were infused with normal salt solution with happy results.

Milk for Infants of the Poor.—During the past summer attempts have been made, especially in Chicago, to find a food for poor infants which might be superior to sterilized or pasteurized milk. It is believed that sterilization greatly deteriorates the food value of milk, causing (1) coagulation of the albumen and consequent difficulty in digestion, (2) loss of the emulsion of the fats, (3) change of sugars to caramel, (4) splitting up of lecithin and nuclein and change in the soluble salts. Pasteurization does not alter the milk so markedly, but is also admitted by many reliable authorities to be a necessary evil. G. F. Palmer (*N. Y. Med. Jour.*, September 8, 1900) urges that no amount of heating can purify a foul milk for the toxins and bacterial products are extremely resistant, and hence a comparatively clean milk is absolutely essential to infant feeding. If one can be sure of reasonably pure milk the advantages of modified raw milk must be admitted. The author first made sure of a good supply of clean certified milk and then modified it according to the rules usually given by the addition of cream and milk sugar. He, however, began with rather larger percentages of proteids and decreased as the age of the infant increased in imitation of normal lactation. The food was packed in sterile jars and placed in large buckets of ice in which it was carried home. These methods were carried out at a diet kitchen in Chicago, and although 700 applications for food and medical care have been made during the summer only three deaths have occurred. The purity of the milk is vastly more important than the degree or character of the modification, and it is therefore incumbent on charitable institutions for children, or better, upon the city government, to insist upon a pure certified milk supply.

Treatment of Gastroenteric Infection of Chil-

dren.—Since the chief cause of gastroenteritis is infection, the primary indication is to empty the intestinal tract of all food and bacteria. Nature attempts this by regurgitation and vomiting of food taken and by causing a serous diarrhea. M. E. Fitch (*Med. Times,* September, 1900) gives small doses of calomel every half hour till there is a yellow stool. Irrigation of the bowel is also at once performed. A gallon of warm sterile water is used, if much mucus is present, adding a little sodium bicarbonate. The temperature should be from 100° F. to 110° F. and the bag held about three feet above the child. The catheter should be inserted as far as possible and the flow continued until it returns clear. In prolonged cases a cool fluid such as one-half-per-cent. lysol or thymol may be used and is often strikingly successful. The feeding of the child is extremely important. In the acute stage milk should be avoided. The white of an egg beaten up in cool water and sweetened with sugar of milk is good. Later sterilized albuminized food, as broths, can be given in small doses with the white of egg. Sterile water should be given *ad libitum.* Antipyretic drugs should not be used. Cold applications to the abdomen are grateful, but a piece of flannel should protect the skin. In the chronic cases, the prognosis is not good. The bowels must be kept clean. Stomach and intestinal lavage are important and inunctions of olive oil with a little alcohol or chloroform are helpful. Fowler's solution and creosote are used internally.

New Physical Sign in Heart Dislocation.—Acute or chronic dilatation of the stomach is frequently the cause of so much dislocation in the position of the heart, says A. Abrams (*Med. Rec.,* September 8, 1900), that severe dyspnea, asthmatic attacks and even pseudo-angina may result. He calls this difficult breathing sequential to gastric dilatation, gastrectatic dyspnea. Many sufferers from this form of dyspnea make no mention of dyspeptic symptoms, the latter being masked by pressure signs, but the condition is relieved by treatment of the stomach alone. Their distress is sudden in origin, attended by a feeling of weight and pressure in the precordial region and eructations of gas usually mark the relief of the paroxysm. It is believed that these attacks are due to the pressure upward of the heart by a dilated stomach. A case is mentioned in which the patient could voluntarily, by buccal insufflation of the stomach, completely obliterate the cardiac dulness. In the cases above mentioned there was also a decrease in the cardiac dulness with correspondingly enfeebled heart sounds, bearing a distinct relation to the severity of the pressure symptoms. Ferber's sign to detect a dilated stomach was that the tympanitic percussion note found in Traube's space, formed by the stomach beneath the lower border of the left lung, gradually disappears behind the axillary line if the stomach is normal, but may be traced to the vertebral column when the stomach is much dilated. This is not considered very reliable, for the spleen usually interferes with the percussion note of the stomach in that area, especially if the spleen is displaced or enlarged. The author has found that when the heart is dislocated upward by a dilated stomach a patch of dulness and even flatness may be detected in the interscapular region on the left side, about midway between the vertebral column and the internal border of the scapula. The dull area may vary from the size of a dollar to that of nearly the whole interscapular region. It disappears when the patient leans forward, reappears on assuming the erect position and is increased by leaning backward. Bronchial respiration is also heard over the dull area, but ceases when the patient leans forward. The dulness is due to compression of the lung and can be demonstrated by inflating the stomach.

Gastroenterostomy and Gastric Function.—The operation of gastroenterostomy is usually one of necessity to relieve a pyloric obstruction, a perforation or a hemorrhage and the subsequent secretory functions are usually of secondary importance. It is seldom that opportunities are allowed for studying the functions of the stomach for any length of time before such an operation, and then continue the observations subsequently to detect the results upon the gastric functions. C. S. Fisher (*Med. Rec.,* September 8, 1900) has reported four cases coming under his care which were operated upon by Dr. R. F. Weir. Detailed examinations were made of all cases for several months before and after operation. One case was that of a benign pyloric stenosis with dilatation. The principal symptom was an intense, spasmodic and remittent pain. Repeated examinations showed a hyperacidity, an impaired motility and considerable dilatation. After operation the case was followed for fourteen months and the results show that the pain had been entirely relieved, the dilatation diminished, the motility was still impaired and the hyperacidity had increased. Another case of benign pyloric stenosis in which there was a gradual increase in the acidity previous to operation with severe symptoms and marked diminution in motility, made a good recovery after the operation, his nutrition improved, the pain ceased, but the hyperacidity seemed to continue to increase. The size of the stomach was markedly reduced. A third case of hyperacidity which caused a pyloric spasm and moderate dilatation was followed for some time with increasing symptoms and an operation of expediency advised. For six weeks after the operation the hydrochloric acid remained normal. Then as a result of mental distress it increased temporarily, but the symptoms never returned. A fourth case of dilatation of stomach without pyloric obstruction and with movable kidney is reported. She was under observation for about four years previous to the operation, and during that time there was a slow gradual diminution in the hydrochloric acid secretion,

there was marked atony and large quantities of fermenting material always present. After the operation the patient began to regain flesh, her pains disappeared and except for occasional attacks of fermentation she has been well since (one year). Notwithstanding the evident improvement in her physical condition the degeneration of the glandular structures of the stomach have continued for there is now no free hydrochloric acid present. The size and position of the stomach remain about the same, but the motility has apparently improved. It thus seems that when the stomach wall has been the seat of a chronic irritation leading to the hypertrophy or atrophy of the glandular structures, an operation which relieves the obstruction will not influence this chronic inflammation which continues. Symptoms do not return, for the immediate cause of distress has been removed, and either hyperacidity or subacidity can exist in stomachs without giving any subjective symptoms. Freedom from symptoms in cases of subacidity depends entirely on the activity of the muscular wall. Furthermore, it seems that the stomach returns to a normal condition of size and motility in cases in which these disturbances were due to obstruction. The regulation of the intestines is one of the best results obtained by gastroenterostomy. These cases are representative of a type in which the operation is not one of necessity but expediency, and hence it is all the more important for the physicians to know what improvements in the symptoms and conditions can be offered the patient.

Treatment of Hemoptysis.—J. E. Frazer (*Therapeutic Gazette*, August, 1900) outlines the treatment for pulmonary hemoptysis in vogue in his practice. The basis of treatment rests on the principle of reducing the intravascular pressure at the site of the hemorrhage. This may be done in two ways: (1) By acting on the heart-beat, the primary origin of all blood-pressures; (2) by acting on the vascular approaches to the wounded vessel. Morphine acts better than any other drug to slow both the number and force of the full and rapid, bounding pulse-beats. Contraction of the vascular channels in front of the lesion is well brought about by ergot. Ergot is allowable, however, only when the bleeding is from vein or small arteriole. In fact, the use of ergot is very often rendered unnecessary as morphine alone is quite sufficient to stop the bleeding. Besides, as unstriped muscle is easily fatigued, it would not be possible to continue the use of the ergot for a long while. The author administers half a grain of morphine hypodermatically—never less than a quarter of a grain, for these patients are very tolerant. Hemorrhage having ceased, the most important point in the whole treatment is to prevent recurrence. An important point to remember in this connection is that after a certain interval the heart will pull itself together and beat with increasing speed and power causing the hemorrhage to recur. Therefore it is necessary to keep the pressure constantly at or below the point at which the hemorrhage ceased. This, of course, means constant supervision, using morphine supplemented by ergot when necessary. The injections may be repeated every two, three, four or six hours as indicated and the interval between them can gradually be increased after the first day or so. Drugs per os give very discouraging results, as they do not seem to be properly absorbed. Chloride of calcium has been used occasionally with success in patients whose blood showed a lack of clotting power. In the great majority of cases, however, it is unnecessary. As for additional means of treatment, rest in bed is a necessity. Too little time is usually allowed for this. In a minor hemorrhage in which but a few ounces of blood are lost, at least five to seven days ought to be spent in bed. For severe hemorrhage, fully several weeks are necessary for the ill effects of the bleeding to be tided over. The diet should be light and cold. The use of purgatives is a mooted question. Where the bleeding has been slight, with no immediate prospect of recurrence for some hours at least, a saline aperient at the commencement is useful; but where the heart's action is excited, this should be strictly interdicted. The action of speaking may usually be disregarded. Cough, if troublesome, may yield to regular doses of chloral or codeine. Pain in the chest generally yields to counterirritation. Pain in the abdomen, if muscular in character, quickly succumbs to firm cross-strapping; if internal, it is probably due to intestinal gout, as described by Haig, and yields readily to sodium salicylate. This condition seems to be due to the injection of morphine. Vomiting seldom takes place, but should it be present and severe, it will be relieved by one-twelfth grain of cocaine. Antimony and ipecac, being too depressing, must never be used. Should the bleeding be arterial the treatment differs in that ergot is inadmissible. In bad cases with high blood-pressure there is small chance of success. When morphine seems to have had but slight or transient action in slowing the heart-beat, aconite has frequently given good results. The ice-bag causes slight effect in slowing the beat and is hardly worth the discomfort it causes. Digitalis may be of use in very mild cases, but has no advantage over morphine in slowing the heart. The minor, impure hemorrhages, in which the sputum is slightly stained with blood and pain and oppression in the chest are felt, are improved by a sharp, saline purge followed by a few doses of ergot.

Syphilis and Diabetes.—Alfred Fournier (*Bull. de l'Acad. de Méd.*, August 20, 1900) reports the case of a girl with syphilitic father attacked at the age of six weeks with a persistent coryza, papulo-erosive syphilides on anus and genitals, and ulcerations in the mouth. Antisyphilitic treatment resulted in a cure, but when seven years of age the girl suffered from a marked

diabetes. All ordinary treatment was of no avail, but the diabetes was promptly cured under specific treatment.

Abdominal Hysterectomy for Ovarian Tumors.—Quenu and Longuet (*Revue de Chirurgie*, July, 1900) narrate the history of nine cases, of which the following one is typical. A woman, aged forty-eight years, whose previous uterine history as to menstruation and childbirth was normal until one year ago, when abdominal swelling was noticed. Examination revealed cystic tumors of both ovaries, the right hand one occupying the abdominal cavity as high as the umbilicus, the left one occupying the iliac fossa, the uterus was displaced downward and backward. The diagnosis of bilateral cystic tumor of the ovary having been made, a hysterectomy with bilateral ovariectomy was done, after the removal of ascites; the tumor was found to consist of multiple papillomatous vegetations involving the large mesentery, the pelvis, and the uterus; the removal of the entire mass which was difficult to accomplish, was followed by a perfect convalescence. With this case and eight similar ones, all successfully operated on, as texts, they draw the following deductions: That total abdominal castration for neoplasms of the uterine adnexa is justifiable, the gravity of the operation being less than usually believed, the mortality in their experience being *nil*. That this procedure has great technical advantages over other methods; the facility with which the ovarian cysts are first isolated and removed, and all adjacent adhesions broken up, being among the prominent advantages; moreover, post-operative accidents, such as intestinal occlusion, are thereby obviated, with a greater guarantee of absolute cure. The indications for total abdominal castration are as follows: (1) Cysts and tumors of the ovaries complicated by inflammation of the uterus, peri-uteritis and salpingitis. (2) Cysts and tumors of the ovary with a uterine involvement. (3) In bilateral cysts and tumors of the ovary, where owing to the size of tumor, or its involvement of adjacent tissue, it is impossible to separate readily the mass from the uterus. The operation is contraindicated when the ovarian tumor is unilateral and occurs in a young woman; when the uterine tissue is not involved; and when one can secure the proper enucleation of the ovarian mass by less heroic measures.

Alcohol a Poison Not a Food.—The therapeutic value of alcohol has long been a matter of dispute between clinician and theorist. Usually it is the former who poses as its advocate, but Kassowitz (*Deutsche med. Woch.*, August 9-16-23, 1900) comes to the fore with a sweeping denunciation of its use and affirms that for a period of ten years he has administered none of it in his practice. Having formerly been in the habit of giving it freely, he considers himself qualified to draw conclusions and is of the opinion that it deserves no place in the therapeutic list. It is useless as a food for it is essentially a protoplasmic poison and therefore incapable of entering into combination in the body, while the belief that through its oxidation it is capable of effecting economy of the body's fat or albumin stores rests on an error of observation. It is true that on an alcohol diet less nitrogen is excreted, but this does not mean that a saving of the body tissues is going on, the fact is simply that owing to its destructive action the alcohol inhibits metabolism, the damaged protoplasm being less able to take part in the vital processes, while at the same time through its benumbing the higher centers the organs innervated by them are less able to functionate normally and oxidation is less active. In view of the numerous other antipyretics and stimulants at command, there seems no valid reason for employing an agent like this, the deleterious action of which on the heart muscle, kidneys, liver, arteries and nervous system is so universally admitted. As a true fuel-saver in febrile and asthenic states, sugar, which may be readily administered in the form of fruit juices, ices, sweetened lemonades, etc., answers every requirement and experiments with the ergograph have shown that after its absorption a rapid and very noteworthy improvement in muscular vigor and tone takes place which of course includes the heart action. As a stimulant camphor surpasses alcohol in its promptness of action and the complete absence of all disagreeable by-effects. It will be a real advance when it is universally recognized that no substance can play the double rôle of foodstuff and poison and that only toxic and never nutritive properties are to be ascribed to alcohol.

Roentgen-Ray Therapeutics.—As the applicability of the Röntgen-rays is being extended from the field of diagnosis alone to that of treatment, new factors in their activity are being recognized. Sträter (*Deutsche med. Woch.*, August 23, 1900) calls attention to the fact that in addition to the intensity of illumination produced, the penetrating power of the rays is of importance. This depends on the nature of the tube used, and he proposes a terminology by which this faculty may be arbitrarily expressed. Soft tubes are those the rays of which are principally absorbed by the skin and muscle, while those able to penetrate down to and through the bone are to be denominated as hard. These characteristics may be recognized by the nature of the shadow of the hand, for instance, thrown on the fluorescent screen. With a soft tube the outline of the soft parts is very distinct, but with increasing hardness it becomes fainter and even the bones are so brilliantly illuminated as to be less plainly visible. In illustration of the importance of the recognition of this variation in penetrating power of different tubes, the author cites a case of psoriasis treated by the rays. The lesion on one arm was completely cured by five applications with a soft tube, while that on the other was entirely unaffected by similar treatment with a hard one.

Empyema of Highmore's Antrum.—M. Halle (*Berl. klin. Woch.*, August 27, 1900) in reviewing the different methods of opening the antrum in suppurative disease says that many disadvantages adhere to the customary procedure. In draining by the way of the canine fossa it is true that the cavity is opened at its lowest point, yet cures in less than six months are rare, due no doubt to the communication with the mouth, which allows of constant reinfection with the numerous bacteria of the buccal mucous membrane. The continuous pressure of pus or of iodoform gauze in the mouth soon becomes very disagreeable to the patient. The same objections may be urged where an alveolar socket is chosen for the outlet of the secretion. The author recommends the following procedure: The mucous membrane of the lower nasal chamber on the diseased side is cocainized. A special trocar is then introduced close to the septum and allowed to pierce the outer wall close above the floor of the nose. Irrigations with boric acid solution to be followed by insufflations of iodoform are then used, at first daily, later at longer intervals. The advantages of this method can be summed up as follows: (1) The operation is simple, rapid, and does not demand an anesthetic. (2) An abnormal communication with the mouth is not made. (3) The patients are not troubled with the taste of iodoform. (4) A rapid and complete cure is assured.

Heroin in Whooping Cough and Phthisis.—After describing the chemical characteristics of heroin M. Loewenthal (*Phila. Med. Jour.*, September 8, 1900) reports in detail 13 cases in which he has used the drug. Three of the cases were of pulmonary tuberculosis and ten of them were of whooping cough. In the cases of tuberculosis the heroin was given in doses varying from 1/8 gr. t. i. d. to 1/30 gr. b. i. d. according to the action of the drug on the patient. Two of the three cases of tuberculosis improved in every way. The patients' cough diminished until practically absent, they slept better, and gained in weight. Expectoration ceased and appetite increased. Their temperature came down to normal. The duration of the treatment in these two cases was three weeks. The third case of tuberculosis improved some at first but soon got worse and died. The ten cases of whooping cough in which the writer used heroin ranged in age from eleven months to eight years. In several of the cases all other remedies had been tried in order to relieve the paroxysms of coughing without result. Heroin was used in doses of from gr. 1/125 to gr. 1/75 every three or four hours, the size of the dose being varied according to the age and the condition of the patient. In one or two patients heroin hydrochlorid was used hypodermatically. The results were all that could be expected in most of the cases, as there was relief from the paroxysms of coughing and the patients were able to sleep well. There were, however, two cases of the ten in which the drug did not act well, in fact, had no effect whatever. In one of these cases heroin seemed to aggravate the disease and also caused a pruritus of the anus. The duration of the treatment with heroin in these patients varied from ten days to three weeks. Loewenthal considers heroin to be superior to anything else we have in the treatment of whooping cough.

Rules in Kidney Operations.—M. Mankiewicz (*Berl. klin. Woch.*, August 27, 1900) advises conservatism in all surgical interference for kidney disease and, in case of nephrectomy, recommends extreme care in ascertaining a normal function of the remaining organ. The best way to ascertain whether or not a kidney is functionating properly is to cause an artificial glycosuria by the administration of 5 milligrams of phloridzin and then to collect the urine by ureteral catheterization. In case of disease it has been found that but little or no sugar will be secreted from the affected organ.

Bacillus Coli in Drinking-Water.—The presence of this germ in water is an undeniable evidence of sewage pollution and it may be found when the contamination is so slight that it cannot be appreciated by chemical tests. In an examination of 509 specimens J. H. Linsley and B. H. Stone (*Med. Rec.*, September 1, 1900) found the germ in seventy-eight, only thirty-one of which were condemned by chemical findings. The presence of the colon bacillus indicates that the contamination is of comparatively recent date and that it probably came from the surface. The search for the typhoid bacillus in water is carried on with much difficulty and results are very uncertain, but if there are no colon bacilli it can at least be said that the typhoid germ is absent. In a number of towns where typhoid fever has broken out no typhoid bacilli were found in the water-supply; it was, however, infected with colon bacilli. The authors conclude that waters in which the bacilli coli communis are found to exist for any length of time are dangerous.

Conjoined Tendon and Cure of Hernia.—J. A. Blake (*Med. Rec.*, September 1, 1900) claims as a result of numerous observations on the cadaver that the conjoined tendon (which is usually understood to be the insertion of the lower fibers of the internal oblique and transversalis muscles, extending along the ilio-pectoral line laterally for a variable distance from the rectus insertion) does not extend for more than five-eighths of an inch laterally from the insertion of the rectus; in the majority, the extent was less than half an inch; in some subjects its extent was inappreciable; and in all cases it consisted of only scattered muscular or tendinous fibers. The true conjoined tendon is ordinarily such a weak affair that it is negligible in operative procedures; it is only exceptionally that either it or the transversalis is included in the sutures in the Bassini operation, excepting

that the sutures placed in the neighborhood of the internal ring may include the transversalis. The main reliance in radical cure is in the internal oblique, and efforts should be made to restore the parallelism of its fibers to Poupart's ligament; this may be done in nearly all cases by separating the internal for a short distance upward from the transversalis fascia and the transversalis fascia and the transversalis aponeurosis, and then, thus having loosened it, it may be drawn down by the sutures to Poupart's ligament. As a rule it is futile to attempt to draw down the transversalis aponeurosis, since this structure is normally deficient for a considerable distance above the ligament.

Collecting Urine from Ureters.—M. L. Harris (*Annals of Surgery*, August, 1900) states that only two methods are valuable, *viz.*, ureteral catheterization and the use of the urine segregator. There are three prerequisites for the successful catheterization of the ureters: (1) An unobstructed urethra of sufficient size to permit the introduction of the instrument; (2) the bladder must have a capacity and tolerance for 120 to 150 cc. of fluid; (3) the fluid must remain transparent a sufficient length of time to permit the catheter to be introduced. These conditions apply equally to all uretero-cystoscopes; to the Kelly method, which is applicable only in the female, conditions 2 and 3 do not apply. The disadvantages of catheterization are that bladder capacity and bladder tolerance differ: that it is not always possible to keep the fluid in the bladder clear enough to permit the passage of sufficient light for distinct vision, the transparency of fluid often being interfered with by blood and pus; that sometimes it is impossible to catheterize the ureters; that the catheter may become choked up; and, finally, that infection may be carried to a previously healthy ureter and kidney despite all caution. To prevent bleeding in the use of the catheter it is advisable to first inject into the bladder fifty to sixty cc. of a five-per-cent. solution of suprarenal extract, allowing it to remain ten minutes; this is washed out and followed by fifteen to twenty cc. of a two-per-cent. solution of cocaine, which is allowed to remain about six minutes; if spasm of the bladder exists, from any cause, precede the above method by injecting the following into the rectum to relieve spasm: Antipyrin, one gram; Tr. opii, one cc.; water, ninety cc.; this requires thirty minutes to act and leaves the base of the bladder quite anesthetic. In the use of the urine segregator, the conditions essential to its successful use are much the same as those for the cystoscope; thus the urethra must admit an instrument the equivalent in caliber of a No. 24 French sound; the bladder must be large enough to allow the segregator to be opened within it; this presupposes a bladder capacity of at least 150 cc. As the sense of sight is not needed to locate the ureteral orifices, the transparency of the bladder fluid is not essential. This constitutes a great advantage. Before using the segregator the bladder should be thoroughly cleansed with a boracic-acid solution; in men, the prostate should be massaged during irrigation of the bladder so that the subsequent introduction of the lever may not press out any pus to find its way into the bladder; the same method, already mentioned in catheterization, of suprarenal extract washing, followed by cocaine solution into the bladder, is here employed. The advantages claimed for the segregator are that it enables one to collect all the urine from each kidney without contamination; it obviates the danger of infection of a sound ureter or previously healthy kidney; it permits a differential diagnosis of certain tumors of the abdomen; it determines which kidney is diseased, giving us the functional capacity of each; and it informs us whether or not the bladder is infected.

Pathological Physiology.—Pathology in its broadest sense, writes Isaac Levin (*Med. Rec.*, September 1, 1900), is a group of sciences studying the structure of a disease organism, pathological anatomy; its chemical composition, pathological chemistry; and its functions, pathological physiology. In this latter we study not only the abnormality of the function of a certain organ, but also the influence such an abnormality has on the rest of the organism. The function may be abnormal by changing its character or, retaining its character, by changing in degree. For example, the heart with a valvular lesion forces some of its blood back into the venous system and thus its function is changed in character, but if the heart merely becomes weak it decreases its work and its function is changed in degree only. In the circulation we must also consider active and passive hyperemias, local anemias, the constituents of the blood, vessel changes, etc. The function of the respiratory organ may be changed in three ways: The air-tubes leading to the alveoli may be obstructed (tumors, bronchitis, etc.), the alveoli may be filled with some other substance than air (pneumonia, edema, etc.) or the musculo-nervous apparatus may cease to work properly. In any case the whole organism is deprived of its necessary supply of oxygen and is unable to get rid of the rapidly accumulating carbonic oxide. Dyspnea tends to increase the oxygen supply, but it has a bad effect on the organism. Digestion, metabolism, excretion and heat economy play important parts in the study of the patient. Clinical data are not sufficient, because we seldom meet with disease of one organ when the rest of the body is normal; so we must resort to experimentation and pathological physiology becomes synonymous with experimental pathology. It is indispensable to progress in the treatment and prevention of disease, and to it is already due our knowledge of the hygiene of food, immunization, and the prevention of epidemics.

Impotentia Virilis.—The chief symptoms to be combatted are those arising from the male genitals causing the neuresthenia so often witnessed in this affection. Chief among these symptoms are premature ejaculations, weak erections, pollution, spermatorrhea and prostatorrhea. Very frequently two or more may be combined. Zabludowski describes the therapy of these affections in the *Berlin. klin. Woch.* (August 13, 1900). Most of the afflicted patients could refer their troubles back to masturbation and other abuses and perversities *in venere*, while others laid the blame on early gonorrheic processes. In a few cases the cause could be traced to long-continued local treatment of gonorrhea, such as bougies, electrodes, cold sounds. Enuresis diurna accompanied many of the cases. Hypochondriasis was invariably present, especially marked on those days in which defecation was absent. The chief method used in treatment was the systematic massage of certain parts of the genital regions followed by massage of smaller and larger portions of the entire body. The object is to stimulate the entire vasomotor system increasing the tone of the blood-vessels. The self-reliance of the patient is also favorably influenced by this treatment. The technic is as follows: The patient, lying on his back, has each of his testicles gently manipulated by the operator. Care must be exercised never to grasp either testicle at opposite points, for in that case pain is caused. Then the manipulation gradually extends along the spermatic cord and also along toward the bulb of the urethra, and the perineum. Finally, the inner surface of the thighs is massaged. In various positions of the patient, *i. e.*, while lying on his side or on his abdomen, all these processes are carried out. Then follows massage of the lumbar and sacral regions carried out by means of pummeling with the fist, although not too severely. Then pressure and massage along the occipital, cervical and intercostal nerves follow. In all these manipulations the most time and care are necessary where painful areas are located. It has been found that, after the simplest palpation in the genital regions carried on through a few sittings, the sensitive areas become greatly diminished, and that the atonic condition of the skin which had easily broken out in clammy perspiration before, became sounder and more elastic. The resisting power of the muscles likewise increased. During treatment it is advisable for the patient to abstain from attempts at cohabitation for about six to eight weeks. The patient may exercise by walking, wheeling, swimming and riding horseback. With great nervousness combined with loss of weight, a short while in bed is advantageous. Change of scene is also advisable. Douches every morning with water at the temperature of the room keep the skin in good active condition. In cases of nocturnal pollution it was also found advisable to change the hour of the evening meal and also decrease the quantity of fluids taken before retiring.

THERAPEUTIC HINTS.

Sodium Phosphate in Urticaria.—*Wolff* gives the phosphate of soda internally, every three hours, in doses of sixty to seventy-five grains, or less in infants, to cure urticaria within the space of twenty-four hours. Locally he prescribes at the same time, as a lotion, a mixture often employed in America for eczema:

℞ Calamine Prep. } .....aa 3iss
Zinc Oxidi.... }
Ac. Carbolici..... 3ss
Aquæ Calcis..... 3xv
Aquæ Rosæ..... 3ivss.
M.

In infants, the quantity of carbolic acid ought to be reduced according to age. In chronic urticaria the phosphate of soda taken after each meal in the dose mentioned causes uniformly a rapid relief, but relapses often occur; indeed, the patients ought to continue the use of this drug until the tendency to relapse has entirely disappeared. Sodium phosphate is particularly efficacious in urticaria of a gastro-intestinal origin, which is often the case.

Bed Treatment of the Acute Psychoses.—*Serieux* and *Farnurier* of Paris warmly advocate rest in bed as being as important in acute mental disease as in any other acute disease. The horizontal position best favors the circulation in the brain and thus aids in overcoming the cerebral and constitutional exhaustion which varies as to cause, but is present in a large proportion of cases. The muscular system is relaxed, the motor centers rested and peripheral stimulation reduced to a minimum, while psychical repose is provided at the same time. When generally adopted, very beneficial results will undoubtedly be reported changing the clinical aspect of various forms of psychoses.

New Local Anesthetic for the Ear.—Aqueous solution of cocaine and eucaine having proved so unsatisfactory when applied to the tympanic membrane as anesthetics, the use of aniline oil and alcohol as vehicles, as first tried by *Albert A. Gray*, should prove a boon to aurist and patient, as paracentesis is stated to be entirely painless five minutes after the anesthetic is employed. Ten drops of the following preparation are injected into the external auditory canal and allowed to flow to the membrane:

℞ Hydrochlorate of cocaine..... 5 parts
Dilute alcohol..... 50 "
Aniline oil..... 50 "

Granulations of the tympanum can also be removed painlessly, first cleansing and drying the parts before using the solution. In case of thickened and hardened membranes the following formula is more effective:

℞ Hydrochlorate of cocaine..... 10 parts
Absolute alcohol..... 30 "
Aniline oil..... 70 "

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

TROPICAL DISEASES AND OUR NEW POSSESSIONS.

Medical men in the United States, whether connected with the army or navy or not, had practically no knowledge or experience on the subject of tropical diseases or of common diseases occurring under tropical conditions which they were suddenly called on to treat when the United States acquired the Philippines and Porto Rico. The diseases which were prevalent among our soldiers in the Philippines were, in the order of their frequency, diarrhea and dysentery, malarial fevers, typhoid fever, and smallpox. Intestinal affections were the most prevalent and caused the largest number of deaths. Malarial fevers were second in order of frequency, but were not as malignant as it was expected they would be. Typhoid fever came next, after intestinal diseases, as a cause of death. Smallpox prevailed as an epidemic when Manila was first occupied and the troops were promptly infected, but the disease was soon controlled. Of these diseases, diarrhea and dysentery were due largely to the climate, to the heat and rains, and to the lowering of vitality consequent on heat-exhaustion. With care in the matter of diet and with avoidance of exhausting labor in the heat of the day, and of exposure to chill, these diseases should not exist unduly in the Philippine climate, but dysentery in its various forms is there always present. It must be remembered that the troops consisted largely of young men who knew nothing of the requirements of the climate, who were doing arduous work under the most adverse circumstances, and who were "trying" all the new drinks, fruit, etc., of the country. Smallpox and typhoid fever are said by some not to be dependent upon the climatic conditions of the Philippines, but smallpox is endemic among the Filipinos. Pemphigus in Luzon is of frequent occurrence and sometimes is extremely serious. In addition to the above, cholera, beriberi, and the plague are present to a greater or less extent in the Philippines, as well as in the Hawaiian Islands. Leprosy is deeply rooted in the Philippines, while the leper settlement at Molokai in the Hawaiian Islands is well known. These four last mentioned diseases, together with the yellow fever of Cuba and Porto Rico, are those against which the United States must be especially on its guard.

Our possessions in the East are, of course, not as extensive as those of England and other countries, nor have we held them sufficiently long for the medical men stationed there to do much original investigation. England's officers in India have done excellent work, as shown by some of the papers read recently at a meeting of the Section on Tropical Diseases of the British Medical Association, and presented in this week's issue of the Medical News.

The consensus of opinion on the subject of quinine as a prophylactic agent in malaria was that it was of great value except in those localities where the malaria was of a malignant form. Some investigators reported that they found it of no value as a prophylactic. The study of the metamorphosis of the *filaria sanguinis hominis* in mosquitoes and the transmission of the filaria through them while in the act of biting human beings has been carried out by Captain S. P. James of Travancore, India. He has formed the opinion that the Anopheles mosquitoes, rather than the Culex mosquitoes, are the usual efficient hosts of the filariæ. Another parasitic disease, ankylostomiasis, which has been the cause of a high mortality in certain parts of India, has received the attention of Major G. M. Giles, who has studied the life history of the parasite. He has demonstrated that the full life history of the *anchylostoma duodenale* is an example of dimorphism or heterogenesis. This parasite is considered to be the cause of the serious anemia

which is so common in those ports. The anemia is demonstrated to be caused by the presence of great numbers of these parasites which bleed the patient. Among other diseases which received attention were the various forms of abscess of the liver and a disease called yaws which is said to resemble syphilis.

As our business relations with the Philippines increase so will the necessity of thoroughly understanding the prevalent diseases of the tropics, both that they may be treated successfully and that they may be kept out of the United States.

It is incumbent upon the Government to aid the medical men of the army in every way in the study of these tropical diseases and of the treatment of other diseases under tropical conditions. Germany has an institute for the study of tropical diseases at Hamburg, and England has one at Liverpool. The post-graduate course in Tropical Diseases in the Army and Navy Medical School in Washington offers to our own medical corps, which may be detailed to tropical service, just the opportunity needed to enter this widening field of study. Its possibilities are vast, and the energetic young men of the country only need to have their attention directed to what is going to be a serious problem in medicine to prepare themselves adequately for the future. The more money that the American Government can appropriate now for investigation and for medical training along these lines, the greater will be the safety of her soldiers and merchants abroad and her citizens at home.

THE HAND AND THE GERM.

Little by little the apparent invincibility of the micro-organism has been shown to be a superstitious fallacy and the ubiquitous pus and infection producers have been ousted from one after another of their microscopic strongholds. After the uncertain reign of the carbolic spray, unreliable in its results and cumbersome and disagreeable to use, the simple application of heat, moist and sufficiently prolonged, has shown itself adequate to absolutely ensure the sterility of instruments and dressings, while that almost impregnable nidus for germs, the catgut suture, yields to the cumol disinfection without losing any of its virtue. And now a practicable method has been published (Katzenstein, *Centralbl. f. Chir.*, July 14, 1900) which makes it possible to efficiently sterilize the almost hopelessly delicate silk and lisle thread catheter without impairing either its finish or vitality.

But however much has been accomplished, the bacteriological battle still goes fiercely on in another quarter and the surgical strategist finds that in his own person his microscopic foes occupy a last citadel from which it is well nigh impossible to dislodge them. The very diversity of the different methods of hand-disinfection in use, Kelly's Weir's Ahlfeld's, Fürbringer's, Mikulicz's, gloves of cotton, leather and rubber, the wax and paraffin coatings of Schleich and Menge, sufficiently evidences the inefficiency of each.

In considering the technic of the various means of chemical sterilization, in which the in the proposals of Mikulicz, Schleich and Säng- subjected to a more or less prolonged immersion in disinfecting fluids, it is interesting to note the prominent rôle in the process ascribed to alcohol which is supposed to be a valuable synergist either through its fat-dissolving power or directly as a germicide. That both these views are erroneous, however, is well shown by Braatz (*Münch. med. Wochenschr.*, July 17, 1900) who calls attention to the fact that alcohol is really a very poor solvent for human skin-fat, 100 gm. dissolving only 0.07739 gm. in seventy hours, while many other substances that surpass it in germicidal power are practically less efficacious, and he attributes its value solely to its faculty of penetrating readily into the minutest furrows and interstices and then by its affinity for water facilitating the subsequent entry of aqueous antiseptic solutions.

The tendency to replace chemical disinfection by thorough mechanical cleansing is prominent in the proposals of Mikulicz, Schleich and Sänger. The former advocates simply protracted scrubbing with an alcoholic solution of green soap; Sänger has devised a soap of great mechanical efficacy on account of the sand incorporated in it, while Schleich's preparation, having resin soap as a basis and marble-dust as a detergent, contains a mixture of wax and paraffin pastes which is supposed to form an impregnable coating over the skin after the mechanical cleansing has been effected by the other constituents. In connection with these it is instructive to note the results of the experimental researches conducted independently by König and Blumberg (*Münch. med. Wochenschr.*, July 24, 1900), and Paul and Sarway (*Münch. med. Wochenschr.*, July 31, 1900) which establish

definitely the fact that more of the purely mechanical means are to be depended on to sterilize even artificially infected hands, and that of the chemical methods those having a mercury salt as prime agent are probably the most effective. The former authors strongly advocate the use of an aqueous 3-1000 mercury ethylendiamin citrate solution in place of the customary bichloride, as being less injurious to the skin and having greater penetrating power.

Haeger (Händereinigung, etc., Basle, 1900), in his discussion of gloves utterly condemns those of cotton, for the operator's use, and relegates them to the attendants, orderlies and nurses for whom they ensure a relative sterility. Leather gloves previously soaked in antiseptic solutions are much more reliable and for the first fifteen minutes are sufficiently impermeable to germs to be used with safety. Rubber gloves come nearer to the mark, but still are open to the danger of accidental rips and impede the operator to a degree depending on the perfection with which the natural conformation of his hand adapts itself to the conventional sizes supplied and hence also fall short of the ideal of combining absolute security with wholly unrestricted movement and tactile sense. The various coatings, paraffin, gutta-percha, etc., are totally unreliable and not adapted to general use.

A review of the results obtained in this field leads but to one conclusion, that no matter how carefully we sterilize our instruments and dressings, by neither mechanical nor chemical means can we bring our hands into a sufficiently germ-free state to promise ourselves immunity from infection, and the only other method at command, that of wearing gloves, is also far from perfect, owing to the demands of operative technic, for the thinner and less hampering they are the greater is the risk of tearing. Under these conditions the only remedy seems to lie in the most scrupulous avoidance of contact with infectious material rather than in any reliance on methods of subsequent disinfection. The prophylaxis involves two factors: one, the habitual use of gloves whenever suspected material is to be touched, and the other, the immediate vigorous cleansing of the hands when accidentally infected while still moist and before there has been time for the deeper layers to be invaded by the germs. This includes also the most careful toilet of the hands. A rough, chapped and abraded cutaneous surface defies the most persistent efforts at cleansing and the effect of the daily use of harsh alkali soaps and immersion in bichloride solution is to be counteracted only by a regular treatment with suitable emollients.

Inspired by a delusive optimism the surgeon has long been working in the hope of finding some agent powerful enough to be absolutely fatal to the germ and yet leave the skin intact, an *ignis fatuus,* for the requirement postulates the ability to precipitate albumin and the superficial epidermal cells must inevitably fall a prey long before the deeper-seated organisms are reached. The time has apparently come when we must acknowledge that further search for antiseptic combinations for hand-disinfection is fruitless and that innovations in technic are hardly to be counted on to bring much improvement. Through its inherent characteristics the hand cannot be either temporarily or permanently freed from its germs, for no matter how scientifically planned and carefully executed the mechanical cleansing, nor how energetic the chemical germicide, there will still remain countless numbers of micro-organisms snugly ensconced in inaccessible hiding-places. Under no other circumstances is prevention so infinitely better than cure, and it is only in the direction of constant and unremitting attention to prophylaxis that a nearer approach to the ideal is to be hoped for.

ECHOES AND NEWS.

NEW YORK.

Yellow Fever at New York.—The "MacClellan" from Havana brought one case of yellow fever to New York this week. The patient was transferred to Swinburne Island.

State Hospital for Tuberculosis.—The Commission of State Prisons at its recent annual meeting adopted the report of Commissioner Mantanye recommending Dannemora as the site for the erection of the State Hospital for Consumptives, and will urge the Hospital Commission to act favorably upon the recommendations contained in the report.

Sued by his Doctor.—Dr. R. H. Greene of this city is suing W. G. Newman, a prominent promoter, for $1200 said to be due him.

Woman's Medical Fraternity.—During the past year, the women of Syracuse University, College of Medicine, have organized Zeta Phi, the first and only women's medical fraternity in this country. They esteem it an honor that Dr. Eliz-

abeth Blackwell has consented to become a charter member, she having been graduated from this college and the first woman to receive the degree of M.D. in America. The purpose of the fraternity is to bring the women of the medical profession into closer touch with one another.

Typhoid in Women's Hospital in Syracuse.—The annual epidemic of typhoid fever has broken out in the State Custodial Asylum for Feeble-Minded Women at Syracuse and twelve persons are down with the fever, including the resident physician.

New Dispensary for St. Batholomew's.—A six-story building, to be occupied as a dispensary, will be erected by the St. Bartholomew's Church Corporation, at 215 and 217 East Forty-second Street, a plot 50 by 92, adjoining the church's present mission house. The cost of the new building is estimated at $200,000.

Four New Electric Ambulances.—Four automobile or electric ambulances are now building for private hospitals in this city. The Roosevelt, Presbyterian and New York Hospitals are making the experiment. St. Vincent's Hospital has had an electric machine for several months. The new gifts to Roosevelt are 7 feet 6 inches long, which is about eighteen inches longer than the ordinary horse-drawn ambulance, and weigh 4800 pounds each.

Rewards of Lawyers.—A distinguished lawyer in this city, in a recent number of the *New York Law Journal*, published some interesting statistics of the practice of law in New York. The practice of criminal law is not considered in his statistics. Taking the last July calendar of the Supreme Court in the First Department this investigator finds that there were 11,230 cases on it which were divided among 2190 lawyers or firms. Nearly 1000 of these lawyers had only one case and more than 2000 of them did not have as many as six cases to try in a year. His figures show that only five law firms in this city had more than 100 cases, and among these five were found only one of the great law firms of twenty-five years ago. Of these five firms three represent large corporations which, from the nature of their business, necessarily have many cases in court. The great law firms of other days have not held their own in this branch of the profession. The bulk of court work has passed into other hands and they are fast becoming firms of solicitors. From the statistics published it is shown that 21 lawyers had upward of 50 cases, 60 lawyers had upward of 20 cases and 104 lawyers had from 10 to 20 cases. The writer suggests that time is sure to bring about a more marked division than now between lawyers who try cases and those who do not, and he believes that the former will ultimately be recognized as a class of advocates. He says: "The average income of men of our profession does not equal $5000 a year. An advocate who could earn $100 a week trying cases would earn the average income of the profession." He makes no mention of what the lawyers make "on the outside."

PHILADELPHIA.

Smallpox in Pennsylvania.—Smallpox still persists in western sections of the State. The schools and Sunday-schools in Erie have been closed because of an epidemic of the disease.

Many Pharmacists Fail.—At a recent examination held by the State Pharmaceutical Board there were 53 candidates for license as regular pharmacist and 42 as qualified assistant. Of the first number only 14 were successful and of the latter only 20 received a license.

Impure-Food Dealers Prosecuted.—The courts are dealing summarily with the above class of venders, four out of sixteen cases being disposed of by pleas of guilty or by conviction. The articles include butter, milk, and flavoring syrups.

Physician Unjustly Censured.—The body of a child dead of diphtheria lay by an open window for fifteen hours in a house on Annin Street, the house not being placarded. The family physician, Dr. Nebeker, was censured by the Board of Health for delay in notification. An investigation showed that the delay was due to the post-office failing to properly deliver the letter of notification mailed by the physician, thus exonerating him from all blame.

Extension of Maternity Home.—An amendment to the charter of the Jewish Maternity Association, lately granted by the courts, allows of an enlargement of the Society's work. A gynecological ward and operating-room will be added, these being urgently required by the institution to care for the increased number of patients applying.

Philanthropic Physician's Bequests.—Dr. Detweiler, of Reading, who died recently, disposes by will of a large property. Having a large income from other property the doctor had for the last fifteen years given the entire income from his medical practice to charity.

A New Healer of the Blind.—Mr. H. N. Casson, who is said to hail from New York City, is preparing to heal the blind population of this staid Quaker hamlet. He dispenses two medicines, the "brown" and the "green," and talks glibly to reporters. It is stated that an offer to treat the inmates of the Pennsylvania Industrial Home for Blind Men was promptly refused by the Superintendent of that institution.

Water Filtration.—The experimental filter plant at the Spring Garden Pumping Station was put in operation September 6th in the presence of the mayor and other city officials. Chemical and bacteriological tests of the filtered water and of the various filtering materials will follow. It is earnestly hoped that this marks the beginning of the end of Philadelphia's notoriously un-

healthy water-supply. The public-school buildings of the city have been equipped with filters during the summer.

Case of Filaria Sanguinis Hominis.—An interesting case of filaria, the second case met with in this city, is now at the Pennsylvania Hospital. The patient is a sailor from the West Indies, twenty-two years of age, recently operated upon by Dr. John H. Gibbon. The filariæ were found in large numbers and were confined to the lymphatics of the spermatic cord, the scrotum not being involved.

CHICAGO.

The Bacillus.—This is the name of a new monthly periodical published under the auspices of the Illinois Medical College. Its editor is Dr. Fred. C. Zapffe.

Dr. Murphy's Place Filled.—Dr. Alexander H. Ferguson has accepted the Chair of Surgery and Physical Surgery in the Chicago College of Physicians and Surgeons, recently vacated by Dr. J. B. Murphy.

Evanston Hospital—The endowment fund of this institution is rapidly increasing, $25,000 having already been subscribed. Before the remodeling can be completed and the desired contagious disease ward constructed, the directors need $20,000 more.

Pure-Food Law.—This law is not clearly understood by the laity. It is intended to protect the buyers against imposition. If a person wishes to buy oleomargarine for butter, chickory for coffee, or dilute acid for vinegar, he is at liberty to do so, but the law stipulates that such articles shall be labeled. The work of the Illinois Pure-Food Commission should be commended.

American Academy of Railway Surgeons.—The Seventh Annual Meeting of the Academy was held in the State Senate Chamber, St. Paul, Minnesota, September 5th and 6th, under the Presidency of Dr. Charles A. Wheaton, of St. Paul. Fifteen papers were read and freely discussed. There were twenty new Fellows elected. The officers for the ensuing years are: President, Dr. D. S. Fairchild of Clinton, Ia.; First Vice-President, Dr. W. L. Estes of South Bethlehem, Pa.; Second Vice-President, Dr. W. J. Mayo of Rochester, Minn.; Secretary, Treasurer and Editor, Dr. T. B. Lacey of Council Bluffs, Ia. Chicago was selected as the place for holding the next annual meeting, the date to be fixed by the Executive Board.

Northwestern University Medical School.—Dr. John B. Murphy has accepted a professorship in Surgery and Clinical Surgery in the Northwestern University Medical School, Chicago Medical College. Dr. Murphy has been appointed Surgeon-in-Chief of Mercy Hospital with the direction of the surgical teaching in that hospital. He will give two clinics each week at the hospital. The hospital now contains 260 beds with abundance of clinical material. A new amphitheater with a seating capacity of 300 is in progress of construction. Dr. Archibald Church has been recently appointed Professor of Nervous and Mental Diseases in Northwestern University Medical School, Chicago Medical College and head of the Neurological Department.

GENERAL.

Obituary.—At Hackensack, N. J., September 8, 1900, Dr. William A. Hillebrecht in his twenty-seventh year.

Poison in Glazed Wares.—A Frankfort newspaper calls attention to the fact that for some time past certain kinds of silver-mounted glass and porcelain wares, such as cups, glasses, jars, vases, etc., have been placed upon the market. The silver on these articles is applied by means of a galvanoplastic process, in baths which contain very large quantities of potassium cyanide. As glazed wares have innumerable hairlike cracks, this deadly poison enters these cracks, and the articles, beautiful to look at, become a severe menace to the health of anybody using or handling them, and especially as it is impossible in the course of manufacture to remove this poisonous residuum. Only a short time ago a very severe case of poisoning resulted from the use of such ware. These goods are chiefly exported to the United States from Frankfort, Berlin and Stuttgart.

Diphtheria from the Horse.—Dr. L. Cobbett reports, in a recent number of the London *Lancet*, the finding of a bacillus, closely identified with Loeffler's diphtheria bacillus, in the secretions of a horse. Dr. Fraser, health officer of Portsmouth, attended a little girl with diphtheria and found, on looking for the cause of the disease, that a pony of her father's was ill with a purulent and bloody discharge from the nose. The toxic action of the isolated bacillus was similar to that of Loeffler's bacillus and its toxin, from culture, behaved as does the toxin of this microorganism. This discovery serves to point out another source of infection for diphtheria and also offer some interesting side-lights on the subject of antitoxins.

Havana's Yellow Fever Problem.—Governor-General Wood has appointed a board of immigration consisting of Drs. Gorgas and Havard and two Cuban physicians to draw up resolutions concerning immigrants. Since July, 1899, 26,000 immigrants have arrived in Havana and 10,000 are expected during the next two months. There were fifty deaths from yellow fever in Havana during the month of August. While the general health of the city is better than ever before, there is a comparatively large number of cases of yellow fever. Owing to the large number of immigrants this is unavoidable. Seventy-five per cent. of the total number of cases were among immigrants who had been in Havana less than a

year. The municipality will consider the advisability of raising money for the sanitation of the city.

Hydrophobia Scare.—The mayor of Wheeling, W. Va., has issued a proclamation taking effect September 3d that all dogs must be confined or muzzled. Two deaths from hydrophobia have occurred and it is hoped that a panic, such as was created four years ago in that city, when many people were bitten and a number died, may be averted.

St. Louis City Hospital Alumni.—This Society met September 6th. Drs. G. Campbell and C. Loeb read papers.

Southern Surgical and Gynecological Association.—The meeting of this Association will be held in Atlanta, November 13th, 14th, and 15th, under the presidency of Dr. A. M. Cartledge of Louisville. Members of the medical profession are cordially invited to attend.

The Galveston Disaster.—Latest reports from Galveston show that the extent of the hurricane was more widespread than at first thought. The number of deaths will probably reach 5000. Of these some are physicians of the city. Those who were uninjured are overtaxed with the amount of medical and surgical work which is necessary to be done. The greatest danger that could happen to Galveston and the United States is the outbreak of yellow fever in the afflicted city. The Government has already sent Health Officers to try to avoid such a contingency.

The Plague.—Recent reports of the plague situation at Glasgow are assuring. New cases are being reported each day, yet they are occurring singly and among those under the observation of the Health Officers of the city. At the present time about twenty cases have been isolated and 150 persons are under strict surveillance.

In India the plague situation remains much the same. This week's reports confirm those of last week, and tend to show that with both plague and famine, India's people, in certain provinces, are suffering greatly. It is reported that the mortality from the plague is at least 1000 a week. The Red Cross and other relief societies are ministering to some 3,000,000 people.

Doctors for the Navy.—A naval medical board of examiners for examination of candidates for admission to the medical corps of the navy is now in session at the Naval Laboratory, Brooklyn, N. Y., and will remain in session for several months. There are now seventeen vacancies in the list of assistant surgeons. Congress at its last session passed a law taking assistant surgeons out of the steerage and making them ward-room officers as soon as they enter the service, giving them the rank of junior lieutenants and the pay of assistant surgeons in the army. Candidates must be between the ages of twenty-one and thirty. Circular of information can be obtained on application to the Surgeon-General of the Navy, Navy Department.

Gynecologists and Obstetricians.—The thirteenth annual meeting of the American Association of Obstetricians and Gynecologists is to be held in Louisville, Ky., Tuesday, Wednesday and Thursday, September 18, 19 and 20, 1900. The presidential address will be delivered by Dr. Rufus B. Hall of Cincinnati. The following papers are announced: "Erroneous Objections to Bilateral Inguinal Celiotomy," by Dr. A. Goldspohn of Chicago; "Round Ligament Ventrosuspension of the Uterus," by Dr. D. Tod Gilliam of Columbus; "A Satisfactory Method of Suspension of the Uterus," by Dr. Robert Morris of New York; "Occasional Incidents in Abdominal Surgery," by Dr. W. H. Myers of Fort Wayne; "Dermoid Cysts Complicating Pregnancy, by Dr. T. B. Eastman of Indianapolis; "Teratoma of Ovary," by Dr. W. E. B. Davis of Birmingham; "Treatment of Chronic Cystitis," by Dr. Charles G. Cumston of Boston; "Perforated Gastric Ulcer," by Dr. Henry Howitt of Guelph; "Malignant Disease of Pelvic Organs," by Dr. A. P. Clarke of Cambridge; "Cholethiasis," by Dr. H. E. Hayd of Buffalo; "Surgery of Gall-Bladder," by Dr. A. Vander Veer of Albany; "Surgery of Liver and Bile-Duct," by Dr. W. G. Macdonald of Albany; "Jaundice Following Abdominal Section," by Dr. H. D. Ingraham of Buffalo; "Diagnosis of Ectopic Pregnancy," by Dr. J. F. Baldwin of Columbus; "Extra-uterine Pregnancy," by Dr. W. B. Dorsett of St. Louis; "Papilloma of the Vulva." by Dr. E. J. Ill of Newark; "The Hymen and Virginity," by Dr. J. M. Duff of Pittsburg; "Private Hospitals and Their Management," by Dr. Joseph Price of Philadelphia; "Extirpation of the Rectum and Sigmoid per Vaginam," by Dr. John B. Murphy of Chicago; "Post-rectal Tumors," by Dr. J. F. W. Ross of Toronto; "Ovarian Fibroma," by Dr. L. H. Laidley of St. Louis; "Rubber Gloves in Surgery," by Dr. C. C. Frederick of Buffalo; "The Ligature and Dry Sterilized Catgut," by Dr. J. H. Carstens of Detroit; "Contraindications to Intraperitoneal Use of Normal Salt Solution After Laparotomy," by Dr. Frank F. Simpson of Pittsburg; "Simple Methods in Pelvic Surgery," by Dr. J. B. Deaver of Philadelphia; "Treatment of Fibroids in Non-Pregnant Uterus," by Dr. E. F. Fish of Milwaukee; "Acute Senile Endometritis," by Dr. L. H. Dunning of Indianapolis; "Tubo-ovarian Abscess," by Dr. E. Ricketts of Cincinnati; "Difficult and Obscure Pus Cases," by Dr. W. B. Chase of New York; "Discussion of Pelvic Suppurations," by Dr. Joseph Price of Philadelphia. Other papers are announced to be read by Drs. M. Rosenwasser of Cleveland, C. A. L. Reed of Cincinnati, H. W. Longyear of Detroit, W. P. Manton of Detroit, F. Blume of Pittsburg and L. S. McMurtry of Louisville.

Jacob M. Da Costa, M.D., LL.D.

OBITUARY.

DR. JACOB M. DA COSTA.

The world of medical science loses one of its greatest lights in Dr. Da Costa of Philadelphia, who died suddenly September 12th at his country home, Ashwood, Villanova, from a heart trouble of some years' duration.

Dr. Da Costa was born in St. Thomas, West Indies, February 7, 1833. He was thus sixty-seven years of age. His education as a boy and college student was received in Germany. His medical training was obtained in the Jefferson Medical College, where Dr. Mutter was his preceptor. He graduated at the early age of nineteen, presenting as his thesis a study on Epithelial Tumors and Cancer of the Neck. He then spent two years in the schools and hospitals of Paris and Vienna, entering practice in Philadelphia on his return.

In 1864 Dr. Da Costa was appointed lecturer on clinical medicine at the Jefferson Medical College and in 1872 was chosen to occupy the chair of Theory and Practice of Medicine left vacant by the death of Professor Dickson. He continued to teach for more than twenty years, resigning this chair several years ago to occupy that of Practice of Medicine and Clinical Medicine. For the past few years he has been Professor Emeritus of Practice of Medicine and Clinical Medicine.

Dr. Da Costa's great skill in physical diagnosis was gained in his lifelong work at the Episcopal, Philadelphia and Pennsylvania Hospitals, and from their wards he has contributed much to the advancement of medical science. In 1855 he published his studies on the "Pathology of Acute Pneumonia," and in 1857, the "Physicians of the Last Century," an interesting historical study, appeared. Investigations on "Cancer of the Pancreas" and "Serous Apoplexy" followed in the

succeeding two years. In 1864 his classical volume on "Medical Diagnosis" was put forth. This has continued one of the standard works on the subject, now just appearing in its ninth edition. Numerous shorter contributions from his pen have been published in most of the prominent medical journals of the country.

In the field of the natural sciences closely related to medicine Dr. Da Costa was an enthusiastic worker. He joined the Academy of Natural Sciences of Philadelphia the year of his graduation, working with such masters as Leidy and Cope. He was also a member of the American Academy of Arts and Sciences and the American Philosophical Society. He became a member of the American Medical Association in 1855. As a diagnostician and as an interpreter of the physical signs of disease Dr. Da Costa had a world wide reputation. His private practice was very large and his many interests made him a prominent and honored member of the profession. Not Philadelphia alone but the whole medical world will miss him.

Dr. Da Costa was a facile and accomplished public speaker and was unsurpassed in his special department as a clinical lecturer. His subject was systematically arranged in his mind and in his method of diagnosis by exclusion he would take up each hypothesis and weigh the evidence carefully *pro* and *con,* finally leading the discussion up to the culmination in the elaboration of the actual diagnosis in a manner that riveted the attention of the class, the students giving every evidence of interest and gratification by crowding to his lecture-hall. His language was always well chosen and he never hesitated for the correct word. He was a student of correct diction, and both in his lectures and in his writings showed his familiarity with the English classics. He also showed his wide extent of medical reading by references to French and German authorities, and, as a consultant as well as clinical teacher, he demonstrated the fact that he kept himself well posted in the current literature of his profession. His monograph upon "Harvey and the Discovery of the Circulation of the Blood" also gave evidence of his studies in the literature of an earlier day in medicine.

As his clinical lectures were much sought after he was frequently annoyed by unauthorized reports which were made of his lectures, and which abounded in infelicities of expression or actual errors, which he had no opportunity of correcting. Thus in the last volume of the "Index Medicus" there are sixteen titles of articles ascribed to him, of which at least two-thirds were unauthorized. But this is one of the things that most clinical teachers suffer from and is probably unavoidable. Among his contributions to medical literature not already noted are the following: Inhalation in the Treatment of Diseases of the Respiratory Passages, 1866; On Quinoidine in the Treatment of Intermittent Fever, 1855; A Case of Cerebral Neuralgia Terminating Fatally by Serous Apoplexy, 1859; Cases of Splenic Leukemia and their Treatment by Hypodermic Injections of Ergotin, 1875; Diabetes Insipidus and Its Treatment by Ergot, 1875; Observations on the Action of Narcein (Penna. Hosp. Reports), 1868; Certain Forms of Muscular Rheumatism, Particularly Wry Neck, and Its Treatment (Pa. Hosp. Reports), 1868; A Contribution to the Therapeutics of Acute Rheumatism, based on a Series of Cases Treated with Bromide of Ammonium (Pa. Hosp. Reports), 1869; Remarks on Relapses in Typhoid Fever, 1877; Harvey and His Discovery, 1878; Cases of Starvation Fever, 1879; The Fluorides in Medicine, 1881; The Nervous Symptoms of Lithemia, 1881; Some Points in the Pathology of Tubercle, 1882; On Catarrhal Fever, 1893; Observations on the Salts of Nickel, 1883; The Higher Professional Life, 1883; In Memoriam, Biographical Sketch of Samuel D. Gross, read before the Association of American Physicians, 1884; Diseases of the Pericardium (in Pepper's System of Medicine), 1885; Some Observations in the Use of Hydrochlorate of Cocaine, Especially its Hypodermic Use, 1886; Remarks on the Treatment of Rose Cold and Hay Fever by Cocaine, 1886; Address of Welcome to the Newly Elected Associate Fellows, Centennial Celebration College of Physicians, 1887; The Methods of Medicine in the Near Present, 1887; Biographical Sketch of Dr. Austin Flint, 1887; Address at the Dinner Given to Dr. D. Hayes Agnew by the Medical Profession in Honor of the Fiftieth Anniversary of his Entrance into the Profession, 1888; Researches on the State of the Ganglionic Centers in Bright's Disease (in cooperation with Dr. M. Longstreth), 1880; Relation of the Diseases of the Kidney, Especially Bright's Disease, to the Diseases of the Heart; the Middleton Goldsmith Lecture delivered before the New York Pathological Society, April 18, 1888; the Treatment of Valvular Disease of the Heart, 1888; Professional Aspirations, Valedictory Address, 1891; Functional Disorders of the Heart (Cyclopedia of Diseases of Children, Keating), 1891; Malarial Paralysis, 1891; The Pulmonary Complications of Influenza, 1892; Address before the Harvard Alumni Association, 1893; The Albuminuria and the Bright's Disease of Uric Acid and of Oxaluria, 1893; Rheumatism (article in Am. Text Book of Dis. of Children, Starr), 1894; Cardiac Asthma —Relations to Heart Exhaustion, 1894; The Coexistence of Typhoid and Malarial Infection, 1897; On the Significance of Jaundice in Typhoid and on its Hepatic Complication without Jaundice, 1898; Phlegmasia Alba Dolens, or Phlebitis of the Leg in Pneumonia, 1898; An Interesting Case of Cholecystitis Simulating Appendicitis, 1899; Anomalous Eruptions in Typhoid Fever, 1899; A Case of Typhoid Cholecystitis Ending in Recovery, 1899; Rapidly Recurring Hemiplegia in Acute Lead Poisoning, 1897.

Dr. Da Costa was a widower, his wife having died seventeen years ago. One son, a member of the Philadelphia bar, survives him.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, September 1, 1900.

THE QUARREL BETWEEN THE BOARD AND STAFF OF THE NATIONAL HOSPITAL FOR THE PARALYZED AND EPILEPTIC—UNYIELDING ATTITUDE OF THE BOARD—LEAD-POISONING IN THE POTTERIES—PROPOSED NEW GOVERNMENT RULES—THE MALARIAL EXPEDITION OF THE LIVERPOOL TROPICAL SCHOOL—DISCOVERY THAT ELEPHANTIASIS IS DUE TO MOSQUITO BITES FROM INOCULATION OF THE FILARIA—BRITISH MEDICAL ASSOCIATION—TREATMENT OF FRACTURES—EARLY USE OF MASSAGE AND PASSIVE MOVEMENT ADVOCATED—INSANITY IN LEAD-WORKERS.

The differences between the staff and the board of management of the National Hospital for the Paralyzed and Epileptic to which I referred in a previous letter are no nearer a solution. The board have taken up an absolutely unjustifiable and unyielding attitude. A meeting of the governors and subscribers has been held to consider (1) whether the demand of the staff for direct representation on the board should be granted and (2) whether it is desirable to hold further inquiry into the condition of the hospital. The chairman argued that as it was possible that the conduct of members of the staff might come before the board for inquiry it would be improper that they should sit in judgment on themselves. Of course the answer to this is the occasion on which the conduct of any of the staff required inquiry must be insignificant compared with those in which they can furnish valuable assistance in the deliberations of the board, and it would be easy to make a rule excluding a medical officer from any deliberation on his conduct. Curiously this very board which is accused of mismanagement by the staff appointed a subcommittee to report on these charges and therefore sees no anomaly in sitting in judgment on itself while denying its medical officers not this power—for they modestly ask for only two seats on the board—but the slightest voice in the management of the hospital. Sir Henry Burdett, who is a well known authority on hospital management, commended the plan of St. Thomas', the Middlesex, the Brompton, and the London Hospitals, in which there is a medical committee consisting of the staff and two members of the board of management. He went on to add that, having paid the hospital a visit in the company of the Hon. Sydney Holland, the Chairman of the London Hospital, there could be no question that the arrangements were excellent.

But neither of these gentlemen nor any other layman, however experienced in hospital management, is competent to give an opinion on the charges made by the staff. These are specific allegations of mismanagement, such as insufficient feeding of the patients and deficient supply of nurses. These conditions could never have arisen if they had a voice in the management of the institution. Something more than the board's exculpation of itself is required. If it persists in its unyielding attitude it will not be able, at any rate, to resist the demand for an independent inquiry which the staff now demands. But such should not be necessary. Who are the proper judges as to the sufficiency of the nursing and diet—a number of laymen or probably the most distinguished medical staff that ever gave its services to a hospital?

The cases of lead-poisoning which have occurred in the potteries have aroused widespread attention and even fashionable women, such as the Duchess of Sutherland, have joined in the agitation for preventive measures. The Home Secretary has prepared a draft of amended rules for china and earthenware manufacturers which have been submitted to employers for their consideration prior to formal service. The first requires that the lead must be "fritted"—a process that renders it much less injurious and which can be performed without serious detriment or inconvenience. Rule 2 is that "After July 2, 1902, no material containing lead which yields to a dilute solution of hydrochloric acid more than two per cent. of its dry weight of a soluble lead compound, calculated as lead monoxide, shall be used in any place or process included in Rule 1. The manufacturers think that these rules will seriously cripple them, particularly the second, in competition with foreign manufacturers subject to no such restrictions, and suggest as an alternative the use of dilute sulphuric acid by the workers, which is largely used in Germany, where lead-poisoning is said to be unknown.

The second malarial expedition of the Liverpool School of Tropical Medicine has telegraphed home a most important discovery from Bonny in Nigeria, *viz.*, that they have discovered the filaria which causes elephantiasis in the proboscis of the mosquito. The same discovery appears to have been simultaneously made by Dr. Low in England in mosquitoes brought from Australia, and by Captain Janes in India. The fact that the filaria can live in the mosquito has long been known and Dr. Manson some years ago propounded a theory as to the part played by the mosquito in the life cycle of *filaria nocturna*, but not that the insect directly conveyed the disease.

At the meeting of the British Medical Association Mr. W. H. Bennett read an exceedingly important paper on the treatment of fractures, advocating methods which completely revolutionize current practices. He wrote to a large number of surgeons in England inquiring as to their practice and received about 300 replies. Up to recently passive movement was never used until a late stage; now there is a distinct tendency to discard splints which do not allow of passive movements. Passive movements used within the first two days may be spoken of as "immediate;" from two to four days after fracture, as "intermediate;" after fourteen days, as "remote." Those surgeons who used movements early got

the quickest recoveries. There is a general tendency to the disuse of plaster-of-Paris splints, as these tend to cause slow union and prolonged disability. Nearly half the surgeons who replied had no experience with operative treatment for simple fractures. The risks of wiring the patella are by no means small and do not seem to depend on the method used. Out of 111 surgeons who replied on this point 3 had had fatal cases, 8 had had to amputate, 16 had had suppuration with ankylosis, 5 had had refracture, or cutting of the wire through the bone during attempts at movement, 10 had had recurrent arthritis. Mr. Bennett considered that in fracture of the patella operation could not be looked upon as ideal treatment and that in the future a rational method would be adopted with early splinting and early movement for all cases in which there was an interval of ½ or ¾ inch, while an operation would be performed in cases of wide separation. As to the early use of massage and passive movement those who tried it are much in favor of it and the opposition is merely theoretical. It is the treatment of the future.

Dr. Robert Jones (Claybury Asylum) read a paper on insanity in lead-workers. Out of 1050 male patients at the Claybury Asylum 35 owed their condition to lead-poisoning. The occupations of the patients were painters, glaziers, plumbers, gilders, electro-plate workers, smelters and pottery glazers. The greatest danger prevailed among those engaged in white and orange lead factories; fine particles of the "dust" containing carbonates and oxides were inhaled from the furnaces. In spite of many Factory Acts a considerable number of cases of lead-poisoning occur yearly, frequently from the carelessness of the workers. The symptoms of lead encephalopathy in 19 patients were varied and included blindness (often of sudden onset), attacks of partial paralysis, epileptic or hysterical fits, mania, melancholia, delirium, apathy and dementia. Some of the cases exhibited symptoms like those of general paralysis of the insane. Headache and loss of memory were not uncommon, as well as auditory and visual hallucinations, and delusions of persecution. Epileptic fits occurred in 7 out of the 19 cases. Treatment consisted in administration of abundant proteids, milk, eggs, open air exercise, electric baths, galvanism, and aperients. The majority of the cases improved under this treatment.

CHRONIC INTUSSUSCEPTION—MULTIPLE MYELOCYSTOCELE—TUBERCULOSIS OF THE JOINTS—ANEURISM OF THE ARCH—ESOPHAGOSCOPY—CONGENITAL HIP DISLOCATION—TABES DORSALIS IN CHILDREN—VACCINE INFECTION OF THE EYES—GALL-STONES—ETIOLOGY OF CANCER—UTERINE RUPTURE.

Enderlein, at the Aerztlicher Verein in Nürnberg described the features of a case of chronic intussusception and showed the post-mortem preparation. A two-and-a-half-year-old boy had been suddenly attacked late in March by colic in upper part of the epigastrium and by mucous stools alternating with bloody and normal movements. August 2d when admitted an almost transversely placed tumor was palpable in the left epigastrium, which traveled slowly down the descending colon, became again almost transverse at the left Poupart ligament and two months later prolapsed through the anus. At the point of the prolapse was a valve-like projection, with small lumen admitting at once into the intestinal canal from which normal evacuations had occurred the day before. The invagination began at about the middle of the transverse colon and extended to the anus. The outer sheath presented several constrictions which were the origin of secondary intussusceptions. A sharp bend over the brim of the true pelvis was the seat of several pressure perforations. Much thickening of the bowel was present and the inner surfaces adherent for sixteen centimeters. The ileocecal valve had wandered through the colon from one end to the other within seven months and the prolapsed portion contained the ileocecal valve and partially inverted appendix.

Multiple myelocystocele was presented by another specimen which he brought before the same meeting. A seven-months-old female child had come under treatment for edema and swelling of the abdomen; it was still nursing, hence ambulatory treatment was necessary; no fever; *per rectum* a large cystic, navel-high mass was made out. At the autopsy the following facts were elicited: The tumor was a much hypertrophied bladder; behind this an apple-sized, smooth-walled, elastic cyst between the rectum and the sacrum and coccyx, pressing alike on the bladder and ureters causing hypertrophy, dilatation and hydronephrosis; closely adherent to those bones without a definite septum between, clear fluid contents, numerous connective-tissue septa and many daughter-cysts identically like the parent in character, especially grouped about the lower pole; neuroglia and very many axis cylinders in the walls; single-layer cylindrical epithelial lining. The nature of the condition was a cystocele derived by construction during embryonal life from the spinal cord, especially the central canal. The multiplication of the daughter-cysts, very like ovarian growths, is an exceedingly rare condition.

Rosenberger, at the Aerztlicher Bezirksverein, Würzburg, May 1, 1900, said that too often today we are prone to ascribe to tuberculosis any joint lesion at all obscure, especially in the presence of a history of the disease, immediate or remote. But many other factors may be at work. An acute or old infectious inflammation may create an osseous or periosteal focus which, although quiescent for years, may suddenly be kindled by some external cause. He cited a case of a woman who for eight years had undergone all known surgical treatment of joint tuber-

culosis except resection. When he saw her the diagnosis of syphilis was made from the wide, deeply drawn, shining, radiating, knotted scars; from the presence of two gummatous swellings of recent and, apparently to superficial investigation, of inflammatory origin; from the entirely satisfactory general condition of the patient, notwithstanding her long history, and from the absence of ankylosis in the joint, in fact of much loss of its function. Antisyphilitic treatment proved the diagnosis. His conclusions were that traumatism may determine gummata, just as abrasions of the skin do the inflammatory signs of syphilis, as recent syphilitic scars show tumor-formation when cut, and as uncleanliness and the rubbing of the clothes bring about condylomata lata.

Ewald, at the Gesellschaft der Charité-Aerzte in Berlin, July 12, 1900, presented an aneurism of the arch of the aorta, which had produced a thrombosis of the vena cava superior to the lumen of a quill and thereby established a most interesting collateral venous return, especially over the thorax and abdomen in front.

Reitzenstein (Nürnberg) at the Mittelfränkischer Aerztetag at Fürth, June 30, 1900, rehearsed clinical observations of esophageal conditions and praised very highly the use of the esophagoscope in diagnosis and treatment. Case I.: A von Hacker gastric fistula of six months' standing was exhibited, done for cicatricial stenosis after the inhibition of acid with suicidal intent. The esophagoscope *per oram* and *per fistulam* showed several marked cicatrices. With its aid sounding was done up to 37 cm. through the stomach, and up to 21 cm. through the mouth. The subsequent treatment to be followed was external esophatomy to remove a large high-placed scar and then slow dilatation to the normal size. Case II.: Twenty-two centimeters from the teeth-line the esophagoscope revealed a piece of bone firmly impacted, measuring 3½ cm. long by 1½ cm. wide, absolutely occluding the lumen and producing pressure ulcerations. With the aid of the instrument the body was turned and extracted. Case III.: By means of the esophagoscope was visible 40 cm. from the teeth-line in a man thirty-five years of age, with a history of 2½ years' standing, a smooth patch which did not move with respiration. The esophagoscope and sounds could not be carried any farther in. On withdrawing the instrument there appeared at 37 cm. a slit-like opening, which at 35 cm. passed into another which had respiratory displacement; from here on it was possible to pass the sound into the stomach at 57 cm., a thing impossible before. The diverticulum had a capacity of 50 ccm. and the characteristic chemical condition of its contents.

Mayer (Fürth) showed a six-year-old girl who four years ago had had a forcible reduction of a congenital dislocation of the hip. The result was a slight prominence of the trochanter due probably to the shallow acetabulum and almost perfect gait.

Von Rad (Nürnberg) discussed two cases of tabes dorsalis in children. Each father had had syphilis and the mother of the second patient gave signs of cerebral syphilis. Case I.: Girl, eleven years old, spinal myosis, optic atrophy, concentric limitation of the visual field, disturbances of color sight, Westphal's and Romberg's sign, paresthesiæ, hypesthesia and hypalgesia of the legs, distinct ataxia of the upper and lower extremities, normal bladder function, ulcer-scars in the mouth, lymphadenitis. The onset dated back two years and began with distinct and rapidly increasing optic-nerve atrophy. Case II.: Boy, nine years old, onset with bladder difficulty (dysuria and incontinence), slightly different slowly reactive pupils, normal fundus of the eyes, Westphal's and Romberg's signs, no distinct ataxia, hypesthesia and hypalgesia of the legs, girdle-form hypesthetic zone about the thorax.

Von Forster (Nürnberg) has observed four instances of vaccine infection of the eyes of attendants upon freshly vaccinated children and attributable to the extraordinary activity of this year's virus. The pustules were located in part on the lids and the conjunctiva. The cornea escaped. Confluence occurred in one case and a purulent discharge ensued. Recovery was in each patient prompt and there were no sequelæ.

Von Kryger (Erlangen) presented an epitomized report of the results obtained in gall-stone cases at his clinic during the last few years. Eighteen operative cases had occurred, distributed by years, two in 1894, one each in 1896 and 1898, nine in 1899, five thus far in 1900; five deaths, one each of empyema, liver abscess, peritonitis, carcinoma of the gall-bladder and cholangitis. Improved knowledge of the disease accounts for the greater number of cases within the last two years, but the diagnosis still remains fraught with great difficulties. Not always, not often even, are the pathognomonic signs of jaundice, colic, enlargement and tenderness of the gall-bladder, concretions in the feces, etc., present. Rather oftener does one find merely pain in the abdomen with vomiting, sufficient to draw attention to the stomach or intestines merely as the site of the trouble. So often does this happen that when there is abdominal trouble which cannot be definitely attached to another organ, one should always think of the gall-bladder as a very likely seat. Chief among the conditions for a differential diagnosis are gastric disorders, intestinal lesions, floating kidney, herniæ and genito-urinary affections. Direct indications for operation are enumerated: (1) Frequent brief, rapidly recurrent attacks of colic; (2) intense colic; (3) persistent jaundice; (4) colic ushered in or accompanied by fever; (5) persistent, although probably not very intense, pains in the epigastrium. The aim of the operation is to fix the site, nature and degree of the lesion and then cure it beyond the possibility of recurrence, when practicable. Often several attempts are necessary. The following must be taken under con-

sideration: (1) Primary or secondary cystotomy. The primary method appears to be more and more in favor because with it it is possible to remove the greatest number of stones. (2) Cysticotomy. (3) Choledochotomy. (4) Anastomoses. (5) Ablation of the gall-bladder, the most radical method of cure, but beset by so many dangers as to be rarely resorted to, except in extreme and carcinomatous cases. His own results have up to the present been satisfactory. Fistulæ imply no danger as a rule and heal spontaneously, although slowly. Recurrence appeared in but one case and seemed attributable to the presence of another inflammatory invasion of the gall-bladder and ducts with colic.

Juergens, at the Berliner medicinische Gesellschaft, July 18, 1900, said that in virtue of his report two years ago of having found definite organisms in the bronchi and in and about the tumors of a case of carcinoma of the lungs, he had subjected the matter to further and careful investigations. Above all other things the author denies the truth that the blastomycetes have any causal connection with cancer as set forth by foreign and promiscuous observers. In his own researches he has to the utmost avoided the colorings giving occasion for artificial products. For the search after living organisms in his experience the fresh specimen either in a thin glycerin preparation or washed in safframin is best. His best results were in the heart of an anemic carcinomatous individual where he found (1) numerous small scattered cells very like those found in the lymph-channels very early in their involvement in secondary deposits; (2) small kernel-like bacteria colonies, situated among the discrete cells, some transparent, some large, some refracting the light, on the whole closely resembling the kernels of myxomycetes; (3) organisms with ameba-like processes; (4) various cyst-like organisms, similar to the spores of myxomycetes. All occurred not only among the heart-muscle bundles, but also in the cancer-mass and among the cancer-cells. He attempts no statement as to whether these organisms possess a causal relation to the cancer, but hazards the opinion that they indicate deep-seated and severe disease of the heart-muscle substance.

Siedentopf, at the medicinische Gesellschaft at Magdeburg, May 3, 1900, brought out the following points in regard to rupture of the uterus. As to the mechanics he considers the uterine wall with the onset of normal propulsive pains to be divided into two segments, active and passive. The active segment shortens, thickens, and hardens its wall, cramps its cavity and empties itself of its contents. The passive segment receives these contents by virtue of a gradual thinning of its parieties. When this thinning process has reached a certain degree the contents of the uterus can no longer be accommodated by it, the os uteri opens, the child's presenting part passes through and is born into the vagina. Should this progress of the conception-product be hindered the balance is lost and there occurs an abnormal stretching of the passive zone which may lead to a rupture. For the closer following of the anatomical processes and of the localization of the zones the author offers the results of external and internal examinations. In one case during a Cæsarean section he was able to establish the fact that the external palpable ring, in this patient navel-high, was indeed the contraction ring and upon section of the organ showed that it corresponded with the internal ring, thus differing from Sänger who claims that the external palpable is not the contracting zone or ring. Pressure-necrosis of the uterine substance between the pelvis and the presenting part, the author holds, is not essential to the rupture, because he has seen one rupture, entirely in the cervix, due to impacted transverse position without pressure-necrosis. In this opinion he differs from Freund. A second class of cases of uterine rupture constitute those which for pathological reasons suffer unusual thinning of the uterine walls and might be said to have a predisposition to tearing. A third series of cases comprise those which on account of faulty dilation of the os uteri are subjected to bandages and pressure bringing about cervical tears which extend to the vagina and thence to the pelvic or abdominal cavities. The symptoms indicating threatened rupture are, subjectively, anxiety and continued pain on account of the tension on the uterine ligaments; objectively, the presence of a uterine contractile ring, the stretching of the round ligaments and the character of the pains. Pain ceases as a rule after the rupture and the child is partly or wholly palpable in the abdomen near the uterus or impacted partly in the pelvis. Shock and signs of hemorrhage appear later. The prognosis is dependent upon the site, completeness and incompleteness of the tear, upon lacerations of large vessels and upon later sepsis. Treatment is prophylactic. Avoidance of external pressure to hurry the delivery, recovery of the child by laparotomy when possible, suture of the complete tear, expectant drainage of the incomplete rupture and all possible means to avoid or combat sepsis.

SPECIAL ARTICLE.

DISCUSSION ON TROPICAL DISEASES [1]

At the sixty-eighth annual meeting of the British Medical Association, held at Ipswich, July 31st and August 1-3, 1900, the Section on Tropical Diseases held the following interesting discussions:

Treatment of Malaria by Quinine.—Andrew Duncan in opening this discussion said that while he could not offer many new facts on the subject, he could corroborate those already known and add some fresh evidence in contradistinction to that previously in vogue as to its value in Africa. In regard to the prophylactic action of

[1] From advance sheets by courtesy of the *British Medical Journal*.

quinine, he cited a number of investigators of different countries, most of whom found fewer attacks of malaria in those soldiers who took small doses of quinine than in those who did not take the drug. Duncan's own results in 1889 were that there were fewer cases of malaria among those companies which took 3 grains of either quinine or cinchona daily than among those who took no drugs. In 1896 50 men took 3 grains of quinine and had not a single case of fever. Of the men of the same regiment who took no drugs 6.5 per cent. had malaria. In 1897 50 men took 3 grains of quinine daily and had no malaria, while the men of the regiment who took no drug had 9.8 per cent. of malaria. In the Malay war, in the Ashanti wars and in the West Regions of Africa the quinine proved of no benefit. The results of an inquiry by Mr. Chamberlain and Dr. Patrick Manson prove without doubt that quinine does exert a prophylactic action against malaria, being efficacious in 87.7 per cent. In comparing the prophylactic action of the quinine salts with that of other drugs, it has been found that the evidence concerning arsenic is very conflicting. Some experimenters secured complete immunity by arsenic, while others, Duncan included, have gotten no positive results. With reference to the curative action of quinine, Duncan finds from notes on 367 cases that this drug comes out best of all remedies, requiring the shortest time to stop the attacks and failing least often. In 78 cases quinine required on an average 2.11 days to stop the fever. The next most successful drug was Nim Bark. Berberis, Narcotine, Kreat, Indergao are other remedies mentioned in the order of their value, but none of them equalled quinine. In most cases the quinine was administered by the mouth. In those cases in which no result occurred after several days, it was given by the rectum in 20-grain doses as well. This method nearly always resulted in a cure, and is highly recommended by Duncan. The quinine probably destroys the organism. W. J. Buchanan said that the prophylactic action of quinine and of the other preparations of cinchona, was tested in 1894 in the jails of Punjab with such success that a similar trial of the drug was ordered the next year in all the jails of India. He had no hesitancy from his own experience in saying that the drug had the effect of certainly reducing the severity of the fever attack, although it did not prevent a large number of cases from coming into the hospital. Also that the incidence of fever was much less than among an unprotected community. He cited five experiments and their controls, all of which tend to show that the prophylactic action of quinine is marked. His experience also shows that daily doses of the drug can be administered for long periods at a time without any bad results. Dr. Robert Fielding-Ould said he had found a great diversity of opinion on the question of malaria and quinine when he was in West Africa. He discussed the action of quinine upon the blood and the amebæ. He does not agree with others as to the prophylactic action of quinine, for quinine does not *prevent* malaria, but only attacks the parasites when they are in an early stage of development. He believes that those who take quinine daily for long periods at a time, do so at the expense of their digestion, or with congestion and torpidity of the liver as a result. The best time to give quinine is when the parasites are about to sporulate, or are in their earliest stage. It may be given in a full dose of 15 grains by the mouth, or 3 grains of the hydrochloride hypodermatically. He called attention to the great value of the rectal administration of the drug. If 30 to 40 grains are injected into the rectum in a little water or mucilage of starch, after an enema, the drug is rapidly absorbed and appears in the blood in 10 or 12 minutes. Fielding-Ould thinks that a malaria patient is a standing menace to the health of the community as long as he has parasites in the blood. The drug should be given for some weeks after the fever has gone and until the microscope fails to find parasites in the blood. Dr. Patrick Manson thought that the prophylactic action of the quinine was the application of the drug to the parasite and not an immunizing of the body against the entrance of the parasite. Therefore if it will cure malarial infection it will prevent its development. David C. Rees said that when quinine is administered by injections, these should be intra-muscular and not hypodermic, and if given with antiseptic precautions no sloughs should result. He believes in taking 2 grains of quinine three times a day as a prophylactic.

Filaria Sanguinis.—A paper on the metamorphosis of the *filaria sanguinis hominis* in mosquitoes, especially in the *Anopheles Rossii* and other mosquitoes of the *anopheles* genus was read by S. P. James. He said he had found that from twelve to fourteen days are required for the metamorphosis in the *Anopheles Rossii*. He cited several interesting experiments on mosquitoes and describes the filariæ. A note on the etiology of filariasis was read by Lieut.-Colonel J. Maitland. Attention is called to the immunity of Europeans to this disease, although surely exposed to the bites of mosquitoes as much as the natives. Water may be the means whereby the filaria enter the human system, especially water obtained from shallow wells or pools. The immunity of the European in India is believed to be due to his drinking only boiled or filtered water. It is possible that the young filaria may pass from the mosquito's proboscis into the water and thence into the human system.

Hot-Weather Diarrhea of India.—Major W. J. Buchanan said that this is a very severe form of diarrhea with watery stools. It is not cholera but resembles it. The writer described the clinical picture of a case and reported several cases. As to treatment during the early stage no drugs should be given, and only such food as milk, boiled milk or prepared food, brandy or rum may be necessary. When the stools become fre-

quent and watery, the writer usually gives chlorodyne or camphoridyne, sometimes with small doses of brandy. When the diarrhea has become much less, castor oil will set the patient aright. The diet should be carefully watched. The causes are (1) bacterial and (2) predisposing. The latter are badly prepared food, bad food, improperly eaten food, overindulgence in food or alcohol, etc. The hot weather favors the production of intestinal fermentation and putrefaction. The disease must be differentiated in India from cholera. The diarrhea is not so fatal as cholera, and cramps are seldom present in the diarrhea.

Ankylostomiasis.—Major Y. M. Giles gave the history of this parasite up to 1889, and stated that of the many new points which he was able to bring out by his own investigations, by far the most important was the demonstration of the fact that the full life history of ankylostoma duodenale is an example of dimorphism or heterogenesis. He explained his experiments in detail, and gave a description of the parasite. The rhabdites have never been found by him in drinking, or in any natural collection of water. They were found in great numbers in the fouled soil around villages and hence he thinks that they are carried to food by soiled hands and that that is the commonest method of infection. Prolonged exposure to the direct rays of the sun kills the free stage worms, and burying the embryos also destroys them. They easily succumb to ordinary disinfectants. The writer believes that this parasite is responsible for a formidable mortality and a great amount of chronic illness.

Capt. C. F. Fearnside gave some interesting statistics as to the presence of this parasite in a large number of convicts. He also showed the effect on these entozoa of better hygiene and cleaner food. His figures tend to show that the effects of the ankylostoma are for the most part secondary and not primary. Dr. Leonard Rogers presented a long paper on the great differences of opinion regarding this disease, the sources of fallacy, the definition and classification of ankylostomiasis, its differential diagnosis and the types of anemia in ankylostomiasis and malaria. Oswald Barker said that he thinks that much of the mortality of Burmah, set down to unknown causes, to anemia and general debility, is due unquestionably to ankylostomiasis. He agrees with Major G. M. Giles that the commonest mode of infection is through the medium of contaminated food, and that water has little to do with the matter.

Tropical Liver Abscess.—Colonel Kenneth MacLeod said that spontaneous evacuation of abscess of the liver takes place most commonly by the pulmonary route. He discussed the physical signs produced by a primary discharge into the pleural cavity, and said that the cavity must be drained. He contends that in old standing cases of lung lesion consequent on hepatic abscess, the pathological burden has been transferred from the abdomen to the chest; and that the lung must be treated according to the special indications of the case, and the liver left to take care of itself.

Subhepatic Abscess.—James Cantlie considers this term to mean a collection of pus on the under surface of the liver, between the liver and its capsule, beginning most probably in the lymphatics. He divides abscesses of the liver into three kinds: (1) Intrahepatic abscesses, mostly of dysenteric origin; (2) suprarenalhepatic abscesses situated between the layers of the broad ligament of the liver, commencing as a lymphangitis; (3) sub- or infra-hepatic abscesses, in which pus lies between the liver substance and the capsule, commencing probably as a lymphangitis. He said that it is possible that the lymphangitis may be due sometimes to the results of filarial infection, as empty sheaths of filaria nocturna were found by him in one case of suprahepatic abscess. He was unable to state the reason why the pus selected this region. The few cases he had seen were in persons who had resided in tropical countries. The local signs and symptoms were a tumor in the epigastrium to the left of the gall-bladder and behind the right rectus muscle, perihepatitis with friction sounds showing an increased area from day to day, hepatitis was not marked, nor was the area of liver dulness much, if at all, increased. The general symptoms are some temperature, occasional rigors, generally paresis of the intestine, or loose bile-stained stools and disturbance of the circulation and of the thoracic movements usual in inflammatory changes in this region. The diagnosis of subhepatic abscess is sometimes difficult. Cantlie has found the prognosis good in the cases he has seen. The treatment consists of tapping with a large trocar and drainage with a tube, or incision when there are adhesions. Wm. J. Smith thinks that surgical interference is necessary both for therapeutical purposes, and also in a large proportion of cases to obtain a precise diagnosis. The diagnosis from symptoms presented is difficult. The exploratory puncture and the exploratory laparotomy are two surgical procedures in the radical treatment. Smith prefers the exploratory puncture, as it succeeds and is followed by no bad results. He uses a needle from 3 to 6 inches in length and a syringe with a capacity of 60 to 120 minims. When pus is demonstrated by the needle after 2 or 3 punctures an incision such as will permit the free discharge of the fluid and drainage should be made immediately. The only cases in which he would refrain from operating excluding those in which the patient is much exhausted and almost moribund, would be cases in which there had undoubtedly been a spontaneous rupture of the abscess into the right pleural cavity.

Amebic Causation of Abscess.—As all abscesses of the liver are of great interest Staff-Surgeon P. W. Bassett-Smith reported a case which occurred in England in a man who had not been abroad for two years. The hepatic abscess followed an attack of dysentery, and amebæ were abundantly found in the abscess fluid to the

complete exclusion of pyogenic bacteria. After death recent shallow (probably amebic) ulcers were found in the cecum. The abscess was in the left lobe of the liver. There was an abscess in the right lung which did not directly communicate with that of the liver. The lung was infected without perforation of the serous membrane. There was pericarditis. *Amoeba coli* was found in the abscess fluid two days after the operation, and the pus was sterile. It is probable that the dysentery was directly due to the ameba and that these were conveyed to the liver.

Improvement of Sanitary and Medical Practice in Tropics.—In this paper Ronald Ross called attention to some improvements in medical organization in the tropics which are much needed. He would have special instruction in animal parasitology and in tropical medicine given to all newcomers, and would have the facilities for obtaining literature on tropical medicine increased. Microscopes and other apparatus ought to be supplied the hospitals. There should be better municipal regulations, and original research should be stimulated.

Blackwater Fever.—Dr. George Thin reported a case of this disease and described his findings in sections of the spleen, liver, bone marrow, and kidney. He is satisfied that the patient died of acute malarial fever in which the hemoglobinuria was a concomitant symptom only. Dr. Patrick Manson said that while it may be quite true that hemoglobinuric fever is an expression of malarial infection, he would not decide that it was so merely because the malarial parasite was discovered in a hemoglobinuric's blood.

Cyprus Sphalangi and Anthrax.—George A. Williamson described this insect, which is about the size of an ant, and gave a complete identification of it. The *sphalangi* is met with only during hot weather. Its body is covered with fine hairs which may be the means whereby it carries infection to abraded surfaces. It prefers foul material as food. In early summer winged individuals are met with. The females can and do sting, but the sting in itself is not supposed to be especially poisonous. In Cyprus the sphalangi bite is considered serious, and possibly fatal. Anthrax is common on the island and the carcasses of sheep dying from it are left too often lying where they died. Williamson reported in detail several cases of "sphalangi bite" in which he found large numbers of undoubted anthrax bacilli in the discharge. In all these cases there was a history of a sheep having died of anthrax in the immediate neighborhood a few days before the patient was bitten. He also noted several cases of sphalangi bites in which there was no infection other than one would expect from the simple bite of the insect. Therefore all bites of the sphalangi are not poisonous, only those which carry the anthrax bacilli upon their sting or on the hairs on their body.

Yaws.—Jonathan Hutchinson opened a discussion on yaws, and presented a young man who he believed was the subject of the disease. The patient presented a number of scars and pigment-stained patches, chiefly on his lower extremities. Hutchinson believes that yaws is syphilis modified by race and climate, and that yaws protects from syphilis and vice versa. Dr. Patrick Manson said he did not believe that inoculation by yaws will protect against syphilis nor vice versa.

SOCIETY PROCEEDINGS.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

Held at Paris, August 2-9, 1900.

(Continued from page 397.)

Section on Dermatology and Syphilography.

Eczema and Its Parasites.—Dr. P. G. Unna of Hamburg thought that much of the difficulty in the diagnosis and proper understanding of this affection was due to the absence of any proper classification of the bacterial organisms. He believes that the disease is due to a micrococcus and that a more persistent study of the staining properties of the various associated micrococci would result in the unraveling of the question. Dr. James Gallaway of London spoke of the uncertainties of diagnosis from a clinical standpoint and also of the need that existed for more strictly scientific descriptions of the many lesions usually spoken of as eczematous. In working with one particular type of disease, acute papulo-vesicular eczema, he has obtained, by working on four cases, a coccus which was found in all. These cocci were pathogenic for mice and were closely allied in their cultural characteristics. He concludes that cocci which produce white colonies are found in early and uncomplicated cases of papulo-vesicular eczema, but they cannot be differentiated from staphylococcus pyogenes albus. Later stages of the disease frequently gave the aureus. Dr. Unna's coccus, he believed, was in the former group. Other important factors should be considered. The predisposition of the skin, usually associated with seborrhea, as well as disturbed bodily metabolism were factors not to be ignored. Dr. Jadassohn of Berne thought that the micro-organisms so constantly found were not pathogenic; their presence was accidental. Their development later undoubtedly gave rise to many secondary lesions in the affected areas. Drs. Brocq and Veillon of Paris concurred in that they did not believe that any specific bacterium had been found for the disease; the principal lesion of eczema, the vesicle, was usually sterile and that the complicated later picture of eczema was induced by the secondary infection of the different cocci described by numerous authors as the causative factor of the initial lesion.

Tuberculides.—Dr. Boeck of Christiania called

attention to the peculiar character of a number of cutaneous affections occurring in tuberculous patients. These were probably due to the effects of the toxin of the bacillus tuberculosis acting on the vasomotor nerves. The bacillus itself was almost uniformly absent. The affections were marked by their symmetrical development, in marked contrast therefore to the asymmetry of affections due to the growth of the bacillus itself. Dr. Campana of Rome spoke of the resistance of the skin to the inroads of the bacillus and its ready involvement by the toxins of this organism. He accounted for this on the ground that the bacillus tuberculosis was a better aerobe than anaerobe and that while the structure of the skin had little to do with the problem, its lack of oxygen had. To distinguish clinically, however, between the lesions of the bacterium and those of its toxin was a very difficult matter. Dr. Darier of Paris enumerated some of the clinical features of the tuberculides. They were symmetrical in their development; were always associated with patients infected with Koch's bacillus; they usually appeared suddenly without any rise in temperature; they were usually of a reddish-purple or livid tinge, and might be found in almost any portion of the body. Moreover, they were tender to the touch, although not painful and were liable to be found under various guises and capable of many modifications in their developmental history. In order to account for them three hypotheses have been given, in the last of which Dr. Darier was inclined to believe. (1) Unknown micro-organisms living in a soil first prepared by the development of the tubercle bacillus produced them. (2) They were brought about by the action of the toxin of the tubercle bacillus. (3) They were the results of multiple emboli of the tubercle bacilli.

Syphilis.—Dr. Bulkeley of New York spoke of syphilis associated with other infections. Thus far the conditions were little studied and he advocated a more careful inquiry into the effects that followed from coincident infections when the second disease was local as well as general.

Dr. Ducrey of Pisa divided these combinations into three classes. Those in which the second infection was purely local and gave no general symptoms; those in which the second infection was usually local, but might give rise to general infection, gonorrhea, for instance, and finally those in which the second disease was general, such as leprosy or the infectious fevers. With purely local conditions he believed that they increased the gravity of the specific lesion. Thus when the soft sore is associated with the hard chancre, suppuration and gangrene are much more liable to occur. The infectious fungus diseases were thought to flourish better on a syphilitic soil. As far as gonorrhea was concerned he did not believe that there was any particular effect one way or another, save perhaps on the occurrence of a gonorrheal epididymitis which predisposed the organ to syphilitic invasion. In the eruptive fevers, the coincidence of syphilis and measles and scarlet fever seemed to result in a heavy mortality. This might have resulted from the bad hygiene rather than the syphilis. Ducrey believes that typhoid fever destroys the syphilitic virus to an appreciable extent. Erysipelas seems to have somewhat of the same effect. Puerperal septicemias are badly affected by syphilis, as are also the association of syphilis and tuberculosis and syphilis and malaria. Syphilis and leprosy seem to have no interaction, the one on the other.

Dr. Hallopeau of Paris believed that it would be wise to limit the term "associated diseases" to those in which a modification was brought about by the action of the syphilitic virus. He believed in hybrid forms of disease produced by such interactions. Such could be brought about by the soft chancre, tubercle bacillus, rarely, and epithelioma.

Syphilis and Heredity.—Dr. B. Tarnowsky of St. Petersburg traced the histories of 25 syphilitic families to the fourth generation. He concludes that (1) the second generation suffers the most from the effects of hereditary syphilis; miscarriages, stillbirths, early deaths and general malnutrition were the chief effects induced; (2) the third generation suffers, but in a markedly diminished degree; (3) immunity to the syphilitic virus is not transmitted to the third generation and the diseases recognized as due to congenital syphilis are not present; (4) syphilis of father or mother acquired at the time of conception or during pregnancy is not transmitted as hereditary syphilis to the offspring; (5) the skipping of one generation was not observed; (6) if the children of syphilitic parents do not show signs of congenital syphilis they have perfectly healthy offspring; (7) hereditary syphilis of the third generation is as a rule reinforced by a second infection in the second generation; (8) such a double infection makes more havoc with the third generation than does the primary trouble with the second; (9) to this "binary" syphilis is to be ascribed the baneful degenerative effects seen in endemic syphilis; (10) the effects of the syphilitic virus run out entirely in the fourth generation. Dr. E. Fenger of Vienna does not think that enough attention has been given to the question of reinfection in the second generation in attempting to analyze the occurrence of the disease in the third. Most, if not all, cases which show third-generation invasion will be found to have had second-generation reinfection. Syphilis seemed to exert its greatest force in limiting the number of progeny rather than decreasing their resistance and thus carried out the natural survival law. With reference to the question of immunity among syphilitics he believed that it was much less than had been supposed. Its comparative mildness in endemic localities and great virulence on virgin soil were facts not to be gainsaid, but they did not necessarily prove the fact of acquired immunity.

STUDIES IN SURGICAL TECHNIC, WITH A REPORT ON OPERATIVE SURGERY AT THE CITY HOSPITAL FOR 1898 AND 1899.

By GEORGE EMERSON BREWER, M.D.,

OF NEW YORK;

ATTENDING SURGEON TO THE CITY HOSPITAL; JUNIOR SURGEON TO ROOSEVELT HOSPITAL; ASSISTANT DEMONSTRATOR OF ANATOMY IN THE COLLEGE OF PHYSICIANS AND SURGEONS.

IN April, 1896, the writer presented to the Harvard Medical Society of this city a paper entitled "Operative Surgery at the City Hospital, with a Preliminary Report on the Study of Wound Infection." This communication consisted of a record of the operative work occurring in my first service of six months in that institution, together with a report of a more or less systematic series of experiments undertaken during that period, with a view to improving the surgical technic of the hospital.

That the surgical technic needed improvement will be evidenced by the fact mentioned at the time, that during the first month of this service, of 43 cases operated on for various diseases and injuries, not one clean case escaped infection, and in only seven of the patients already infected did the operative procedure result in wounds which healed without suppuration. As these results were probably the worst ever published, and certainly far worse than any previously observed by the writer, a rigid investigation was at once undertaken to account for, and if possible to correct this unfortunate and mortifying state of affairs.

It should be stated, however, that at this time the hospital operating-room was small, badly lighted, badly ventilated, and wholly unprovided with modern appliances; that there was no apparatus for the proper sterilization of ligature and suture material, and no modern autoclaves for sterilizing dressings, gowns, etc., under live steam. In addition to these disadvantages, our house staff by the system of rotation then in vogue, changed every six weeks, the house surgeon only having had a previous surgical experience of six weeks as junior.

After a brief period of investigation, a large number of errors in technic were discovered, among the most important of which may be mentioned faulty methods of hand disinfection, faulty method of disinfecting the wound area of the patient, rough handling of the divided tissues during operation, frequent contamination of hands, sponges, towels and dressings, through lack of training of the operator and assistants, contamination of the wound by falling dandruff during operation, and by insufficient protection by dressings during the period of convalescence.

These and many other minor errors were gradually corrected during the remaining five months of the service, with only a fair improvement in result, until at last the method of operating without any assistance was undertaken in a few selected cases. The result in these cases was perfect; in each instance union taking place by first intention. Then followed a number of cases in which one assistant was admitted; later two, and finally three. In addition to this a censor was appointed, whose duty it was to watch every step of the operation and to instantly condemn any hand, instrument, sponge, suture or dressing which had become accidentally contaminated. In this way a large number of errors were avoided, and the results began to show substantial improvement. The year closed with a record of 39 per cent. of clean cases having become infected during operation.

In reviewing the results at the close of the paper, the writer made the following statement: "As a large proportion of the patients admitted to our wards are in a wretched condition of malnutrition from syphilis, tuberculosis, chronic alcoholism and insufficient food, it is not surprising that our results should be inferior to those obtained in institutions where the more fortunate classes are treated; for it is a well-known and generally accepted fact that a vigorous and healthy organism can often overcome, without local or general reaction, an amount of infection which would certainly give rise to suppuration and marked systemic disturbance in one whose vital forces were greatly reduced by dissipation or disease. While the writer believes that this fact may account for a certain amount of suppuration following operations on clean cases, it by no means can account for the large number of infections which occurred during this period. I may say, in conclusion, that it is my purpose to continue these experiments, and if necessary inaugurate a series of bacteriological investigations with a view to locating and removing any other sources of wound infection which up to the present may have escaped detection; after which it may be possible to gather some data, which may help to solve the question of how much (if any) unavoidable suppuration may be expected in this class of cases."

As a result of our changed technic the work of our second year showed at once a marked improvement in results. During this period the Department of Charities, as a result of an earnest appeal from our Medical Board, furnished the Hospital with two new perfectly equipped operating-rooms with all modern appliances. A

complete sterilizing room was added with 3 Sprague-Kny autoclaves, instrument-boilers, water-sterilizers, and in fact everything necessary to equip a modern operating-room. An operating-room nurse, trained in the Johns Hopkins Hospital, was secured and placed in charge. At the same time, to test our new apparatus, and to detect further errors in our technic, a thorough bacteriological investigation of our material and methods was undertaken and thoroughly carried out by Dr. Phillip Hanson Hiss of the Pathological Laboratory of the College of Physicians and Surgeons.

A complete record of these investigations, together with the changes in our technic which resulted from them, was presented to the surgical section of the New York Academy of Medicine in a paper entitled "Operative Surgery at the City Hospital with a Completed Report on the Study of Wound Infection," and published in the *Medical Record* of March 13, 1897.

As a result of our bacteriological investigation it was conclusively demonstrated that our material, such as silk, catgut, sponges, dressings, towels, gowns, caps, etc., was absolutely sterile; that our instruments were clean; and that our methods were free from any glaring errors in technic. The three most probable sources of infection still to be remedied were, the skin of the patient, the hands of the operator and his assistants, and the air of the operating-room. The second was completely removed by the adoption of rubber gloves; the third was minimized by the plan of covering all instrument trays and hand solutions with sterilized muslin tents supported by wire frames. Many methods were employed to remove the first, but without any proving bacteriologically satisfactory. Toward the close of the year, the following rules were printed and posted in the operating-room and in each surgical ward of the hospital. These will serve to give a general idea of our methods.

Preparation of Patient.—When possible, a hot bath shall be given the day before the operation, followed by shaving and scrubbing the part for two minutes; soap poultice over night. The following morning, rescrubbing for ten minutes, after which a wet bichloride gauze dressing shall be applied (1-1000); this to be done only by the head-nurse in the ward, after thorough sterilization of the hands.

On the operating table, the dressings shall be removed and the part washed by the house surgeon, for one minute, with soap and sterile water, a pledget of sterile cotton being used instead of a brush; then douched with alcohol, ether and sterile water. Sterile dry towels to be used around wound area. The operator, his assistants, and the operating-room nurse shall wear freshly sterilized gowns. Gauze caps shall be worn in every aseptic case by those in immediate contact with the wound area.

The hands of the operator, his assistants, and the operating-room nurse shall be prepared in the following manner: After cleansing the nails with soap, hot water, and a sterilized nail-cleaner, the hands and arms must be brushed for five minutes with sterilized soap and hot water, then brushed for one minute with a 3 per cent. solution of carbolic acid in alcohol, and rinsed in sterile water. Sterilized rubber gloves shall be worn by all participating in the operation. The ligature and suture material shall be removed from the bottles and handled only by the senior assistant surgeon; dressings and sponges only by the operating-room nurse.

The head nurse of the ward shall superintend the moving of the patient, the adjustment of the blankets and other unsterilized coverings, assist the etherizer, and be prepared when necessary to assist or take the place of the operating-room nurse.

No departure from these rules will be allowed without the permission of the house surgeon.

As a result of these changes, our records during the second year show substantial improvement, as the infection of clean cases during this period was reduced to 9 per cent. The work of our third year was largely devoted to overcoming the results of air infection, which from our bacteriological experiments we felt was a factor at least in some of the infections which had occurred during the previous year.

The favorable effect of glutol or formalin-gelatine powder had been noted in a series of badly infected wounds which had been treated by this agent, and it occurred to the writer that some other form of formaldehyde might be employed as an antiseptic agent in wounds which had been exposed to the air during long operations.

To verify certain statements in regard to the antiseptic properties of formaldehyde gas which had been published in France the writer made the following experiment:

A room was selected in the hospital, the air of which was known to be badly infected. The capacity of the room was about 2800 cubic feet. In this were placed a large number of test-tubes containing gauze soaked with pus from suppurating wounds, also tubes containing spore threads contaminated with *bacillus subtilis* obtained at the pathological laboratory of the College of Physicians and Surgeons. These were placed at a number of levels and more or less completely imbedded in masses of gauze, towels, sheetings, etc. The room was closed as tightly as possible and formaldehyde gas passed through the key-hole in the door from a Trillot generator for one hour. Three hours later the room was opened and the various pieces of pus-soaked gauze and the spore threads transferred to bouillon-tubes; also, scrapings from the floor, sidewalls, window-sills and board-shelves, and the tubes sent to Dr. Hiss for incubation. No growths were obtained in any of the tubes thus inoculated, conclusively demonstrating the powerful antiseptic properties of formaldehyde gas.

The next experiments were in the sterilization of acutely infected wounds with solutions of formalin. This was used in the strength of 1-300

to 1-50 of water, as an irrigating fluid, and also for soaking gauze which was used as a wound packing. Experiments were also made with formalin as an agent for hand and skin disinfection, and finally the plan adopted of wiping all operating wounds with gauze sponges wet with this agent just before suturing, and applying a strip of wet formalin-gauze over the sutured wounds before applying the ordinary dressings.

All of these experiments were reported in detail in a paper read by the writer before the Surgical Section of the Suffolk County Medical Society in Boston, in March, 1898, entitled "Some Observations upon Modern Surgical Technic from an Analysis of 421 Operative Cases at the City Hospital."

As a result of these improvements in our technic, the writer was able to report, at the close of his third year, infection in only 7 per cent. of his clean operative cases.

During the years 1898 and 1899 the writer was on duty 13 months. The total number of operations occurring in his service was 358, which may be classified as follows: Operations on the head, 27; on neck, 22; on thorax and spine, 22; on abdomen and pelvis, 60; on upper extremity, 18; on lower extremity, 117; ischiorectal region, 52; on hernias, 40.

Of the 27 operations in the head, there were 10 osteoplastic resections of the skull for intracranial disease, of which seven recovered and three died. Four for necrosis of lower jaw, all recovered; one excision of upper jaw, recovered; one excision lower jaw, improved; two epitheliomata of lower lip, one recovered, one improved; two excisions of tongue and floor of mouth, one improved and one died; one excision of tonsil, floor of mouth and part of lower jaw, died; one Hartley-Krause operation for removal of the Gasserian ganglion, recovered. Two fractures of lower jaw, wired; one epithelioma of face and one of ear—all recovered.

As the 11 operations upon the brain have already been reported by the writer, with a number of others, in a paper entitled, "Some Observations on Modern Cerebral Surgery," none of the cases of this series will be mentioned in detail.

Of the 22 operations on the neck, there were 3 for abscess, 12 for tuberculous glands, 1 for hematoma, 2 for tumor, 1 sarcoma, and 1 cyst of thyroid, 2 exploratory incisions, 1 for inoperable sarcoma, and 1 for supposed carotid aneurism; 1 ligature of common carotid and 1 tracheotomy for carcinoma. Of these 17 recovered, 2 were improved, and 3 died. Two of the three deaths occurred in patients who were practically moribund at the time of the operation; one of these was tracheotomy in the last stages of carcinoma of the throat, and the other was a ligature of the carotid artery to check hemorrhage in a large ulcerating sarcoma of the neck.

Only one operation of this series deserves special mention and that was in a case referred to the surgical service by Dr. C. C. Ransom, Visiting Physician to the Hospital, with a diagnosis of aneurism of the common carotid artery. The case presented nearly all of the characteristic symptoms and signs of the disease. There was a slight bulging with visible pulsation at the root of the neck on the right side under the lower portion of the sternomastoid muscle. Upon examination a small deep-seated tumor could be felt with distinct expansile pulsation when the thumb was placed at the outer border of the sternomastoid muscle just above the clavicle, and the first finger pressed deeply in the suprasternal notch, the two being then separated about two inches. The patient complained of slight pain with a disagreeable sense of throbbing which often prevented sleep. Under ether anesthesia an incision was made along the inner border of the sternomastoid muscle, and the artery exposed. No aneurism was found, but there was a peculiar and quite unusual anomaly present. The right subclavian artery arose from the junction of the ascending and transverse portions of the arch of the aorta, and passed upward and outward in the direction of the innominate; about one inch to the left of this branch was a large trunk given off from the middle of the arch, which was found to give origin to the right common carotid and the left common carotid and subclavian arteries. The right common carotid described a double curve similar to a letter S, obliquely placed, the first and lower curve with its convexity pointing inward, occupied a position in the suprasternal notch; the second and upper curve, with its convexity pointing outward, was placed above the clavicle, partly behind and partly to the outer side of the sternomastoid muscle. From this point the artery pursued a direct course upward to its bifurcation. The patient recovered from the exploration.

There were 22 operations on the thorax and spine; one case of carcinoma of both breasts, double Halsted operation; two laminectomies—one for fracture and one for Potts' paralysis; two resections of clavicle for deformity following fracture; three cases of mastitis; one axillary abscess; one exploratory operation for caries of spine; one Van Hook's operation for sacro-iliac disease; nine resections or ribs, of which 3 were for empyema, 2 for abscess of lung, 1 for subphrenic abscess, one Estlander's operation and two for exploration; one excision of a large carbuncle of back. Of these 15 recovered, one was improved, 2 not improved, and 4 died; the 4 deaths being the 2 laminectomies, 1 following operation for empyema, and 1 for abscess and gangrene of lung.

Of the 60 operations on the abdomen there were 48 laparotomies. Of these there were 9 appendectomies, 4 cholecystostomies, 1 cholecystectomy for carcinoma, 2 intestinal anastomoses, 2 gastro-enterostomies, 1 gastrostomy, 4 colostomies, 7 for ventral hernia, 1 for tuberculous peritonitis, 2 hysterectomies, 2 salpingo-oophorectomies, 3 for intra-abdominal abscess and 1 for a ruptured ectopic gestation, 1 nephrectomy, 2 nephrotomies, 1 nephrorraphy, 1 suprapubic

cystotomy, 1 large retroperitoneal abscess, 4 for cellulitis and 2 uterine cases.

Of the 48 laparotomies there were no deaths from operation, and in only 2 did death occur during the period of observation, and these were both cases of advanced carcinoma. Death followed operation in two cases of extensive and neglected pelvic suppuration opened externally, and in one case of exploratory nephrotomy where multiple abscesses of the kidney were found.

As a number of interesting cases of this series has already been reported in the *Annals of Surgery*, and as a report of the gall-bladder operations is reserved for another occasion, the writer will mention but one case in detail.

This patient was referred to the writer by Dr. Joseph Collins, attending physician to the hospital. A male, aged thirty-two years, complained of pain in the left side of the chest and abdomen, cough, shortness of breath and fever; duration three months. Upon examination there was seen an enlargement of the left half of the abdomen, extending from the crest of the ilium, upward behind the ribs, and causing a marked bulging of the lower left side of the thorax. This enlargement was found on palpation to be due to the presence of an enormous tumor, occupying the entire left half of the abdomen which was smooth, dense and moderately elastic. An aspirating needle withdrew moderately thin pus. Under chloroform anesthesia an incision was made in the left flank parallel with the lower rib, and the tissues divided through the lumbar aponeurosis. Just beneath this structure was found a thick fibrous mass suggesting a cyst wall. This was incised and about a gallon of pus was evacuated. The wound was thoroughly drained, dressings applied, and the patient placed in bed. All symptoms were at once relieved, and the wound was regularly irrigated and dressed for two or three weeks. As the discharge persisted and the patient's condition did not improve after the first marked relief, he was again anesthetized and the kidney and cyst wall removed through a large König's incision. The vessels and ureter were ligated with chromicized catgut, the wound closed by layer sutures and a small gauze drain introduced. The patient made an uninterrupted recovery and has since been well. An examination of the specimen showed it to be an enormous suppurating cyst developing from the cortex of the upper pole of the kidney and not communicating with the pelvis.

Of the 18 operations on the upper extremity, there were 2 excisions of the elbow, 1 excision of a metacarpal bone, 4 amputations of the arm, 1 at the shoulder, 1 suppurating arthritis of the elbow, 2 cases of cellulitis, 1 lengthening of tendon, 1 neurosis, 2 wiring of ununited fractures, 1 ankylosis of elbow, 1 old dislocation of the shoulder, and 1 chronic relapsing dislocation of the shoulder. There were no deaths in the series; 14 were discharged cured, 2 improved, and 2 not improved.

Of the 117 operations at the lower extremity, there were 28 amputations, of which 3 were at the hip, 9 of the thigh, 4 of the leg, and 12 of the foot or toes; 5 excisions, 2 of the knee and 3 of the ankle; 5 arthrotomies of the knee, 4 for suppurative synovitis and 1 for the removal of a loose cartilage; 1 arthrotomy of the hip; 1 suture of a ruptured tendon of the quadriceps extensor; 7 cases of hallux valgus; 1 exploratory operation for tumor of thigh; 1 excision of a sarcoma of the ilium; 1 tumor of the buttock; 1 wiring of an ununited fracture of the femur; 1 flat foot; 1 case of multiple typhoid osteo-myelitis; 1 tenotomy; 8 for neurosis; 8 Tiersch skin grafts; 17 cases of cellulitis and 29 cases of varicose veins of the leg. There were 6 deaths in the series of 117 cases; 1 occuring 6 weeks after amputation of the hip, suddenly at night without known cause, as the wound was healing kindly; 1 following amputation of the thigh; 1 of the leg and two of the foot. In the sixth case death from uremia followed a simple operation on varicose veins; 11 of the series were unimproved as a result of the operative intervention; 5 were improved and the remaining 95 were discharged well. Of the three cases of hip amputation two recovered, and have been reported in the *Annals of Surgery*. Fowler's operation was employed in the 7 cases of hallux valgus—all with satisfactory result. In the case of multiple osteomyelitis following typhoid fever, there were 2 foci in each tibia and one in the femur opened; 4 healed promptly and one after prolonged drainage. In the case of sarcoma of the ilium, the entire ala was removed down to the ring of the acetabulum. This extensive wound healed very slowly, but the patient was finally transferred to another service on account of a lung tuberculosis and died about six months later without a recurrence.

The arthrotomies of the knee furnish an interesting series. The four cases of suppurating synovitis were all opened freely, washed out and drained; all recovered with a fair degree of motion. The one for the removal of a movable cartilage became infected and later submitted to an amputation of the thigh. This case will be referred to later in our report on asepsis.

Of the 52 operations on the ischiorectal region there were 19 for hemorrhoids, of which 3 were treated by the Whitehead method, 3 by ligation and excision, and 13 by clamp and cautery. There were 20 cases of ischiorectal suppuration, with 8 fistulæ leading into the bowel; 1 fissure ani; 1 inguinal adenitis; 4 ulcers of rectum; 1 prolapse of rectum; 1 hematoma of scrotum; 1 varicocele; 2 hydroceles; 1 tuberculous testes; 1 suppurating epididymitis; 1 external urethrotomy for extravasation; 1 carcinoma of vulva, and 1 carcinoma of rectum (Kraske's); the last case resulting fatally, being the only death of the series.

Of the 40 hernias operated upon, 37 were inguinal and 3 femoral; of the inguinal, 27 were operated upon by the Bassini method; 7 by the Halsted and 3 by the Phelps. Two of the fem-

oral were for radical cure and 1 was for the relief of strangulation. All of these patients recovered, and will later be reported in a series of 100 by the writer.

As there had been during the last four months of 1897 no case of infection in a clean operative wound, although 43 such cases had been operated on, it was hoped that our results during 1898 would be such as to enable us to present a report of which we might be justly proud. We had excluded all sources of infection through ligature and suture material, instruments, dressings, towels, sponges, and irrigating fluids. We had avoided absolutely contact of bare fingers with wound area or anything which could come in contact with it. We had guarded against falling dandruff or dust from our heads, we had protected our instrument trays, hand solutions, water pitchers and irrigators; we had employed the most systematic and thorough methods of sterilizing the wound area; we guarded every step of our operation by an ever vigilant censor, and, at last, to overcome any possible air infection, just before closing each clean wound, we carefully wiped it with a sponge wet in 1-50 formalin, and after suture the wound was still further protected with a strip of gauze wet in the same solution. In addition to this our entire staff was enthusiastic. Each one watched the others for the slightest error in technic and the fullest criticism was invited and welcomed. A stitch-abscess was immediately made the subject of the fullest inquiry, and anything more serious resulted in our suspending all operative work until a satisfactory explanation could be obtained.

During the first month of this year pus appeared in only one clean operative wound, and that is not recorded as an error of operating-room technic, as it was expected and provided for. The patient was an exceedingly old and feeble woman with an advanced epithelioma of the leg. Her condition would not permit of her being prepared in the usual thorough manner and on the operating-table everything was sacrificed for speed of operation. The thigh was amputated at the junction of the upper and middle thirds; the vessels secured, only three or four sutures introduced, the rest of the wound being generously packed. She made a rapid and satisfactory recovery, although pus was present from the first dressing in the drain opening, which nevertheless closed rapidly. Shortly after this a wound made by my house surgeon for the removal of a varicosed vein suppurated; probable exciting cause, excessive bruising and tearing of the subcutaneous tissues. The following month a stitch infection occurred in an internal appendix case operated upon by the writer, without known cause. During August of this year five cases became infected; a veritable storm of infection. It was thought that this might be due to contamination of the wound by our gloves by perspiration, as the weather was excessively hot, or through contact with flies, which was occasionally noticed. Two others occurred during the last three months of the year, making 9 in 105 clean cases, or 8½ per cent.; 1½ per cent. higher than in 1897.

Although the writer had fully intended to make his usual report this year, the results were so disappointing, and after four years of conscientious and almost unceasing effort, so utterly discouraging, that the report was never written. By a careful analysis of the infected cases, it was seen that 8 of the 9 cases occurred in hernia or varicose-vein wounds, both areas difficult to disinfect, while in the former the tendency toward the formation of dead spaces and accumulation of blood and wound fluids renders infections very probable; while in the latter, the hypertrophy of the skin not infrequently retards repair.

These facts led to a slight change in our technic in these cases to insure better drainage. This consisted in suturing the upper and lower thirds of these wounds only, leaving in the middle third a gauze drain which extended upward and downward under the sutures and projected in the middle well above the wound edges. One or two provisional sutures were then introduced in the drained middle third. At the end of forty-eight hours the wound was dressed, the gauze drain removed and the edges united by the provisional sutures.

The results were strikingly satisfactory; as our records for 1899 show, that out of 96 clean operations, only 3 became infected, and in two of these our usual technic was not carried out. The first case was a serious one and I blame myself for the result. The patient was a healthy man, fifty years of age, who had complained of symptoms of a movable cartilage in the right knee joint. He readily consented to an operation for its removal and was prepared in the usual manner. Recognizing the seriousness of an infection of the knee-joint, as well as the susceptibility of its synovial membrane to infection, the utmost care had been exercised to avoid any error in technic. After the patient was anesthetized and on the table, and all of the assistants were ready, in drawing my thin rubber gloves on my hands one was badly torn and rendered entirely useless. I asked for another pair, but was told that none were available. At first I determined not to proceed with the operation, but later changed my mind, as all of the assistants were properly gloved. I again thoroughly disinfected my hands by the Fürbringer method, and proceeded with the arthrotomy. No error in technic was observed; the joint was quickly closed, a large aseptic dressing applied and the leg encased in a plastic cast. All went well for 36 hours, when a suspicious rise in temperature occurred, which was soon followed by other symptoms of infection. The joint was freely opened and drained, but in spite of all our efforts a rapidly developing sepsis occurred requiring amputation of the thigh.

The second infection occurred in a hernia wound which was tightly united without drain-

age by my house surgeon, who feeling sure of his technic asked permission to try one case by that method. The third was simply a small stitch abscess which occurred in a varicose-vein case operated upon by another house surgeon, in which the record does not mention whether it was drained or not.

To briefly sum up the results of our five years of work at the City Hospital: First year, number of operations, 147; deaths, 8; mortality percentage, 5.4 per cent.; infection occurring in clean cases, 39 per cent.

Second year, number of operations, 109; death-rate, 8.2 per cent.; percentage of infection in clean cases, 9 per cent.

Third year, number of operations, 165; death-rate, 9 per cent.; percentage of infection in clean cases, 7 per cent.

Fourth year, number of operations, 191; death-rate, 6.2 per cent.; percentage of infection in clean cases, 8.5 per cent.

Fifth year, number of operations, 168; death-rate, 7.1 per cent.; percentage of infection in clean cases, 3.2 per cent.

From these observations, the writer feels justified in stating, in answer to the inquiry made at the close of his first report in 1896, as to how much unavoidable suppuration must be expected in this class of patients, that, if our technic is perfect, none should be expected, and while he is willing to admit that the resistance of these individuals is doubtless greatly reduced, and that visible infections will occur from a very much smaller amount of infective material than in healthy organisms, still by a perfect, though perhaps an exaggerated system of technic, our results at the City Hospital may be made as perfect as those at any other institutions.

68 West 46th Street.

TOXICITY VERSUS SEPTICITY IN THE INFECTIOUS PATHOGENIC BACTERIA.

By EUGENE WASDIN, M.D.,
OF BUFFALO, N. Y.;
SURGEON UNITED STATES MARINE HOSPITAL SERVICE.

It is now a well-established fact in bacteriology that the pathogenic organisms are hurtful to the animal economy through the action of certain toxins, the product of their physiologic development, which are absorbed from the seat of their colonization and affect the system through the circulation; that these toxins are also elaborated during the growth of the bacteria upon artificial media and may be extracted therefrom in a comparatively pure state; and that, when introduced into the blood of animals susceptible to their influence, they produce the symptoms which characterize the infections with these bacteria. Also, that the infecting bacteria may prove hurtful through their presence in the blood having invaded the circulation from the primary colony.

The former conditions are the "intoxications" and to the latter has been applied the term "septicemiæ," although this does not convey the meaning that the injury results from their active presence in the blood, for it is still from their elaborated toxins that the symptoms of disease are produced.

The classic intoxications are those of diphtheria, of tetanus and cholera Asiatica, in which infections the localized colony of the organism seems to play no further part than the production of toxin, which being absorbed produces the symptoms, the intoxication. In diphtheria the colony rests always at its primary seat, extending only upon the contiguous membrane; there is no invasion of the other tissues of the body, no septicemia; the organisms occasionally found in the adjacent tissues being the result of phagocytic carriage from the mucous surface involved. In this disease the presence of the colony excites a most wonderful local reaction, the leucocytes quickly forming a barrier of protection in the so-called "false membrane."

In tetanus and in cholera there is no such local reactionary collections of leucocytes. In the former the primary symptoms are developed in the nervous centers remote from the seat of infection; while in the latter, although the symptoms may be primarily intestinal, there is no general cellular formation, such as is found in diphtheria, nor does the presence of the bacillus in the intestine seem to determine the changes in the intestinal wall. There is no invasion of the circulation, no septicemia in these infections.

Influenza must in all probability be included in this class, although the isolation by Pfeiffer of his bacillus from the blood in some cases may demand that this disease be classed with the "modified septicemiæ."

The infections which develop septicemiæ more or less prominently are: Lobar pneumonia, due to the bacillus lanceolatus pneumoniæ; typhoid or enteric fever, due to Eberth's bacillus typhosus; "bubonic plague," or peste, due to the bacillus pestis of Kitasato; tuberculosis, due to the tubercle bacillus of Koch, and yellow fever, due to the bacillus icteroides, first isolated and assumed by Sanarelli to be the cause of this disease.

In pneumonia there is ample evidence in the "consolidation" of the development of an active chemotaxis, the toxins inducing a determination of the leucocytes to the seat of the primary colony in the lungs, although this attempt at limitation is not as perfect as that in diphtheria, and the bacillus is frequently found in the blood and other tissues, such as the meninges, pleuræ, peritoneum and pericardium, the result of septicemic invasion from the primary colony.

In enteric fever, in peste, and in yellow fever, this effort at protection, no doubt successful in many cases of pneumonia, is wanting. The localized colony gives little or no local evidence of its presence, but is productive of a primary intoxication of varying intensity, the local injury from which results in the passage of the organism into the circulation, the ensuing sepsis being characteristic of these diseases.

What, then, is this quality in some of the infectious pathogens which determines septicemia? And what the quality in others which limits their presence to the site of the original colony?

At present it is the extent of our knowledge that in the former there is no effort on the part of the leucocytes to form protective barriers in order to limit invasion; while in the latter such protection is afforded. These facts have been explained by the theory that the toxin produced, as well as the cytoplasm of the bacteria, exercises a positive attraction for the leucocytes which aggregate into the "false membrane," "consolidation," etc.; and on the other hand that there may be a negative chemotaxis, one resulting in a repulsion of the white cells, in their disappearance from the seat of invasion, and the consequent entry of the organism into the circulation, and the production of sepsis.

This positive chemotactic influence is not common to all the extremely toxic bacteria, since it is absent in tetanus and in cholera, in neither of which is there septicemia. Septicemia therefore does not depend on the presence or absence of the phenomena of chemotaxis, since two of the infections cited, presenting the evidence of positive attraction, are usually powerfully toxic and are limited to local infection, while two others equally toxic exhibit no attraction and yet are absolutely limited to the primary locality. Further than this there is no evidence of a negative or repulsive chemotaxis.

That there is a purely septic infection there is reason to doubt, that is to say, one as purely septic as diphtheria is toxic. The most recent studies in peste have demonstrated that in this disease we probably have the nearest approach to a purely septic infection;[1] and in typhoid fever the disease must be considered a "modified septicemia."[2] The presence in an organism therefore of a pronounced toxicity seems to be the determining factor in accounting for the absence of septicity, since in all cases the latter is present on the more or less pronounced absence of the former.

Is this quality of toxicity in the infectious pathogens a fixed one to the exclusion of other qualities? Or is it associated in them with that of septicity which may become under certain conditions, the more pronounced of the two?

The facts bearing upon these questions are as follows: The bacillus lanceolatus is frequently found in situations, as in the meninges, pleuræ and pericardium, which indicate it as the cause of the diseased condition of these structures, while the lungs are free from the classic signs of pneumonia, and the mode of invasion of these structures in such cases becomes a matter of speculation, "the avenues of entrance for the cocci are in all probability the nose and mouth, and next most frequently through the maxillary and tympanic cavities and the cribriform labyrinth by way of the vascular and lymphatic routes."[3]

There occurred recently in the hospital service of my friend Dr. Lesage of Paris, France, an epidemic infection from this organism which serves to illustrate the varying degree of toxicity which it may develop as well as its septicity. Among a number of infants ranging from two months upward, there started an acute fulminant disease, resulting, in the first case, in death within forty-eight hours. The symptoms were those of intoxication; there was little prodromic manifestation, the attack usually commencing with fretfulness and convulsions. The temperature did not range high, there was profound impression upon the nervous centers, the little ones dying comatose. Nearly all the children in the ward were attacked; nearly all died; the mortality was startling. Himself a noted bacteriologist, Lesage was alive to the possible infecting cause in these cases, the possibility of their being due to other cause than bacterial intoxication having been quickly eliminated. From each case during the continuance of the disease and from the cadavers there were made numerous plantings of the blood, and of the juices of the liver and spleen, and of the pericardial, pleural and cephalorachidian fluids. From these cultures he was enabled to conclude that the infecting organism was the bacillus lanceolatus pneumoniæ; that it was present in the bronchial mucus in all of them; that it was present in the blood and other tissues in many; that a certain number gave no colonies save from the tubules of the lungs, that is to say, the tissues were sterile, there had been no septicemia. In none of these cases had the symptoms been those of infantile pneumonia, nor did the lungs present any signs of consolidation when examined post-mortem, there being at most a catarrhal bronchitis.

In these there is demonstrated the possibility, nay the fact, of the development of the toxic quality of bacillus lanceolatus to such a degree that death took place from the absorption of the toxin from the colony localized in the lungs, where the organism was found in the bronchial muco-pus, without the classic local reaction and without the invasion of the circulation from the primary colony; *a purely siderante type.* Also the fact of the pulmonary infection, followed by septicemia, in cases presenting no signs of pneumonia, the organisms being found throughout the body; cases of secondary infection, or rather, of intoxication and septicemia. All of the infants developed the infection in the lungs; all showed marked symptoms of intoxication; in none was there a pure septicemia. In some the disease lasted for several days, the septicemic symptoms preponderating.

In epidemic meningitis the bacillus lanceolatus has been found giving rise to the disease, no other organism being present in the sero-pus of the meninges. The point of entrance, in such epidemics, is quite obscure.

From the reported experience it is quite clear that these cases depend on the local colonization

of the bacillus lanceolatus. This then develops a most marked quality of septicity, so injuring the lung tissues that, in the absence of all local reactionary symptoms, a blood invasion takes place and meningeal or other diseases result as a secondary factor, although it may announce the presence of disease.

In diphtheria there is no evidence of the possession of the septic quality by the bacillus of Loeffler. Indeed the active chemotaxic quality is intensely developed in this organism, and clinical knowledge is limited to the classic type of the disease. There is at hand, however, much information relative to the changes in the qualities of this bacillus when cultivated outside of the body. We recognize the pseudo-bacillus—one not exhibiting the quality of toxicity at all—and the existence of a diphtheria bacillus, which, lacking its toxicity, has developed a marked septicity for animals.[4] Further observation may demonstrate similar mutations to those seen in the bacillus pneumoniæ.

In enteric or typhoid fever there is an abundant literature to establish the view that the disease is frequently independent of any invasion of the alimentary canal, since the typical lesions are frequently absent from its mucosæ, and much to indicate a primary invasion of the lungs with secondary sepsis. The toxic quality of Eberth's bacillus is not pronounced, that is to say, to the extent of producing marked local reaction, and since Calmette has described rather characteristic alterations of the glandular follicles of the small intestine in those dead of peste, it would seem more than probable that the glandular changes are due to the toxin, whatever may be the site of the original colony of the germs.

In typhoid the disease quickly assumes the septic type in all cases in which the bacillus develops the septic quality. It is not possible to determine how many cases of incipient typhoid intoxication occur which present only the primary phenomena common to most of these intoxications and result in the arrest of the disease in this stage, or short of the development of a septicemia, whence result all the symptoms of typhoid after the first week, but there must be a great many of them. Nor is it improbable that many acute conditions, ending fatally and presenting no classic pathologic changes, are *typhoid intoxications* similar to those *siderante* types of yellow fever and peste to be mentioned further on. The mutations of the organism of Eberth are known in the number of pseudo-bacilli which have been isolated, but I am not aware of any clinical recognition of the *foudroyant* type of the disease. A recent study of this question has resulted in the conclusion that the bacillus typhosus produces but little toxin (in artificial media) and that typhoid fever must be considered a "modified septicemia."[5]

There is no intention on my part to antagonize the long prevalent views as to the mode of invasion of the germ in typhoid fever, but there can be no doubt that they must be modified, if not entirely abandoned, and that sanitary measures must be directed as much to the prevention of the inhalation of germ-laden dust as to the drinking of polluted water.

In peste, the conclusions of the mixed commission which studied the disease at Oporto, Portugal, during the prevalence of the disease in that city, in 1899, demonstrate that the disease is almost purely a septicemia. M. Calmette, the French member of the commission, in a most learned memoir, states that there are at least two varieties of the disease, the "classic bubonic plague" and the "pneumonic pesteuse." Recognizing the importance of abrasions or cuts in the cuticle as a ready route of entrance for the germ and giving instances of such artificial infections, all of which resulted in septicemiæ, he mentions cases which seemed to originate as *lung infections,* or as pulmonary peste.

These were rare, the larger number seeming to be "bubonic," that is to say, they were septic from the commencement of the disease, the buboes being developed at the time of the first examination. In all of his cases cultures were made from the blood upon their entrance into hospital, and in all cases the bacillus pestis was recovered, provided the planting had been done before the administration of the Roux "sérum anti-pesteuse." He decides therefore that peste is almost a typical septicemia.

There were however a number of cases mentioned presenting primarily the classic symptoms of "bubonic plague," which, to his chagrin, suddenly became complicated by severe pulmonary symptoms and died, although at first they were considered quite benign. Calmette exhibits marked power of observation up to this point in his work, but here he allows the presence of the bacillus pestis in large numbers in the lymphatics leading from the lungs to influence him to the conclusion that these pneumonies are due to an invasion of the lung structure *from the blood,* in which the bacillus is (somehow) primarily located, through the lymphatics which enter, or pass out through their roots, forsooth because the edematous, sodden lung teems with the bacillus pestis.

Nothing can be more far-fetched than this explanation; first, because it offers no opinion as to the mode of original invasion in the typical bubonic cases in which wounds of the cuticle are not present; and, second, it gives too much importance to a pathologic condition in the lungs which is not peculiar to this disease alone and is due solely to the continued influence of the toxins upon the structure of the lungs, directly or indirectly. This results in almost total loss of elasticity of the resilient tissue supporting the terminal vessels. These in turn, losing this support, become congested; there is interstitial edema and a condition of semi-consolidation, only typical of such injury to the elastic tissue of the lungs. This condition is quite common to influenza, in which disease it is frequently erroneously diag-

nosed as pneumonia or broncho-pneumonia.

The organisms forming the primary colony in the lung in cases of peste would increase enormously under such conditions of the lung favorable to their development and the lymph-channels as well as the blood would teem with them. Calmette states that these cases resist the "sérum anti-pesteuse" and are fatal. Similar observations were made by a committee appointed by the Department of Health of Berlin, Germany, for the consideration of plague measures, and mention is made in its report of cases in which death occurs before any appearance whatever of localization, before the patient is even made aware, by pain, of his condition.[6] Dr. Schmidt also encountered notable pulmonary engorgement, with bloody, frothy sputum, and râles, but no evidence of pneumonia in eighteen of twenty-four cases and in all of these the peste bacillus was found in the sputum.[7]

From these facts there are, then, cases of peste which, commencing as a recognized lung colonization, more or less quickly develop sepsis and exhibit the usual signs of bubonic plague; others which exhibit no lung symptoms at first, and are simply bubonic in type, until the later appearance of very grave lung symptoms, which terminate fatally. Whether there may be *siderante* types of peste, Calmette does not determine, but reports[8] from the foci of plague of rapidly fatal cases should attract attention to this probability, and under epidemic influences every case of sudden death should be investigated bacteriologically. The probability of numerous cases of peste of so light a type as to escape medical observation during the prevalence of the disease is clear.

I therefore submit that the theory of Calmette as to the mode of infection in peste is in error, save in the rare cases which he describes as pulmonary, and I advance the facts, as given in this disease and the other infections mentioned, to establish that peste is essentially a respiratory disease; that the bacillus, being preeminently septic, gives rise to but slight local reaction in the lungs and passes readily into the circulation, causing septicemia, the "bubonic" symptoms being *always secondary*.

The bacillus pestis is known to be changeable, and I have seen two isolations of this organism from cases of peste in which the quality of septicity was found wanting when the bacillus was injected into animals, the organisms producing no appearance of disease. If, however, this changed bacillus is placed upon the mucosa of the nares, infection takes place and sepsis results. These observations are not unique in that in no other infectious pathogen has the quality most pronounced, after infection has taken place, been found wanting when the germ has been recovered, but that they demonstrate that reinfection through natural channels serves to prove its specificity and restore its septicity.

With reference to the exhibition of the qualities of toxicity and septicity by the bacillus icteroides in yellow fever the conditions are very patent. From a close observation of the disease in man, both in the tropics and in the Southern States, and of the disease as produced in animals by natural methods of infection, I am convinced, as shown in the conclusions arrived at by the Commission of which I was the senior member,[9] that the bacillus icteroides possesses both these qualities in a marked degree. My observations have demonstrated that yellow fever of the foudroyant type, in which the patient becomes at once desperately ill and dies within forty-eight hours, is due to the intensity of the intoxication from the colonization of the bacillus *in the lungs*, and that in them there is no exhibition of the secondary sepsis, that is to say, of the presence of the bacillus in the blood or organs. Also in the large number of well-developed cases of yellow fever, with possibly lessened toxic power, the bacillus exhibits marked septic power, giving rise to the septic symptoms known as the "third stage" of the disease, the "first stage" being due to the primary colony in the lung tissue, whence the bacillus invades the circulation. The great probability of there being numerous cases of this disease so ephemeral as to escape diagnosis during epidemics, or in endemic areas, is made evident by our clinical experience under such conditions. The disease has been known to exist for months without correct diagnosis because of its mild character.

During my studies in yellow fever I have not observed the pseudo-bacillus icteroides, and I realize that this must be very difficult in view of the close relationship between many of these organisms in their biological and cultural characteristics.

In the infections with the tubercle bacillus of Koch there have been almost inexplicable abnormalities, such as the primary colonization in the joints, in the testes, in the meninges, the pleuræ, or the peritoneum. This has been so marked that many of them have been explained only on the hypothesis that the organism must have entered the body of the embryo through the placental circulation, and there remained dormant, producing disease only when some accident to the tissue in which they may lie is sustained. This cannot explain all cases. In the classic type of tuberculosis of the lung the toxicity of the germ is developed to the extent of the production of an aggregation of cells, the grey tubercles, which limit more or less perfectly the diffusion of the organisms, and thus prevent sepsis or the invasion of the blood and other organs from the primary colony. These limited infections may recover, or they may progress very slowly, unless influenced by some complication. In other cases the reaction at the seat of infection is slight, the bacillus invades the circulation and sepsis results in the deposit of the bacillus at some point or points at which a new colony may be formed with all the expressions of local tuberculosis, the colony in the lung progressing or not to local destruction of tissue.

It does not, however, seem probable that there may be developed the "foudroyante" type of tuberculosis, the tendency being rather to the development of the septic quality of the disease.

Of course, these infections are considered to be pure, and there is no intention to introduce the idea of mixed infection by the use of the terms "primary" and "secondary," as they apply only to the germ producing the specific infection.

From what has been said it is evident that the toxic and the septic qualities coexist in many of the infectious pathogens; that in a few of them the former alone is exhibited, with or without the phenomena of chemotaxis, while in others they are both pronounced; and, finally, that in at least one case, bacillus pestis, the latter quality may be developed almost to the exclusion of the former. Therefore their coexistence would seem to determine that the two qualities are not antagonistic, and yet it is only in the presence of extreme toxicity that we do not have sepsis, and that the less pronounced the intoxication the more readily is sepsis developed. The examples of bacillus pestis which have lost their septic quality, as already alluded to, and that of bacillus diphtheriæ, which, having lost its toxicity, has developed a heretofore unrecognized septicity, demonstrate that, like toxicity, the quality of producing sepsis is inherent in the pathogens, of less potential it may be than the former, and apt to be overshadowed by it.

This quality, evidenced by the presence of the organism in the blood whence it may pass into any tissue, must depend upon some specific injury to the tissues at the seat of the primary colony, which is of such a nature that the invasion of the blood can take place. That this is not dependent on the presence or absence of local reactionary symptoms is shown by the two most prominent of the truly toxic diseases, diphtheria in which there is local reaction and tetanus in which there is not, and in neither of which is there sepsis. Septicity is a factor in the equation of the acute infections which must be recognized, since this recognition will result in an explanation of those obscure points in the natural history of these diseases which have proved veritable stumbling-blocks both to the clinical and didactic teachers.

In such diseases as typhoid fever and gonorrhea, in which the infection may take place from the mucosa of some organ other than the respiratory tract, the septic quality will be as readily followed by sepsis as from infections along this tract. The law, then, in these acute infections, which governs the formation of the types of cases encountered in all of them, is that the infection having taken place, *the type of the disease must depend upon the development in the infecting organisms of the inherent qualities of toxicity and septicity; that if toxicity preponderate there will result the toxemiae, and if septicity be the more pronounced the septicemiae will be produced, since these qualities coexist in each infective germ, the one or the other being exhibited in greater perfection according to environment.*

I fully appreciate the desirability of having at hand more information drawn from experimental work in this matter, but it may not be necessary always in order to present a truth formulated on experimental and clinical study of one infection (in my own that of yellow fever) which can be applied to other infections, to present actual experimental work in those allied infections in evidence. Also that conditions, not theories, having been established in one infection, the laws relating thereto may be applied to all infections in so far as their application can explain the peculiar characteristics of such infections.

The influence of these facts has been materially felt in the production of the curative sera, those infections characterized by mixed toxic and septic symptoms, such as enteric fever, pneumonia and yellow fever, having thus far yielded but slightly to such treatment, while the most toxic, as diphtheria and tetanus, and the most septic, as plague, have been benefited by their appropriate sera. Therefore it appears likely that until it is possible to dissociate these qualities in any specific organism and to utilize the one desired, it will be impossible to produce a curative serum with anything like the beneficence of the diphtheria antitoxin.

TOTAL EXTIRPATION OF THE URETER.

By WILLY MEYER, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS; CONSULTING SURGEON TO THE NEW YORK INFIRMARY.

Total extirpation of the ureter means the removal of the entire canal from a point just below the pelvis of the kidney to its very entrance into the vesical wall. The operation is done either simultaneously with nephrectomy (primary) or some time, sooner or later, after this interference (secondary). The primary operation is rarely carried out. It means for the patient a serious addition to the risk connected with removal of the kidney; it requires more time and, consequently, a longer general anesthesia, both important factors in this particular operation; in cases of suppurating or of tuberculous kidney it will often render impossible the task of maintaining an aseptic condition of the large retroperitoneal wound. Tamponade followed by secondary suture will then become necessary. This complicates the after-treatment and prolongs convalescence. We

shall, therefore, oftener hear of secondary than of primary total ureterectomy.

Inasmuch as the operation is always simultaneous with or consecutive to nephrectomy, the same pathologic condition that had induced the surgeon to extirpate the kidney will be found to exist in the ureter.

Those who have followed the evolution of renal surgery know that conservatism has taken a firm hold in this chapter of our science. To-day the kidney is at the first operation removed only in cases of tumor, primary tuberculosis, and exceptionally severe cases of suppuration; and even in these affections a few authors have recently argued against sacrificing the entire organ. Whether such an attitude is justified, the future will show.

It appears proper to review separately these three indications for primary nephrectomy recognized to-day by the majority of surgeons, with regard to their influence upon a probably following total extirpation of the ureter.

1. *Tumor of the Kidney.*—As a matter of course, only malignant growths come into consideration. Of these I exclude such as did not primarily originate in the kidney. As far as I have been able to ascertain, a case of total ureterectomy for carcinoma or sarcoma of the kidney has not been reported in literature. Of course, if the ureter should appear to be involved in the disease, no surgeon would hesitate nowadays to make his operation a radical one, even if he should be obliged, owing to the serious condition of his patient at the time of the first operation, to wait a few days before doing ureterectomy. Nevertheless, it is evident that in the majority of cases the ureter need not be removed entire. If the latter organ has become involved in the disease to its entire length, the trouble will in almost every instance be beyond the reach of the knife. Thus, ureterectomy in cases of malignant renal tumor will generally be a partial one. The operator will do well, in every instance of this kind, to remove as much of the upper portion of the ureter as he can reach from the wound, without subjecting the patient to an additional operation. If he has done that, he will have carried out what appears to be necessary in the given case.

2. *Tuberculosis of the Kidney.*—In fourteen cases of renal tuberculosis where I had to perform nephrectomy, the ureter was not totally extirpated. In all these the wound closed without leaving a sinus, although scraping and proper treatment of the wound became necessary, now and then, toward the end of convalescence.[1] If materially infiltrated, the proximal part of the ureter was resected as far down as possible; if not especially affected by the tuberculous process, the tube was simply cut off below the kidney and dropped back into the retroperitoneal space. The latter procedure I practised up to several years ago. However, since I have observed a case in which the greater part of the urine from the healthy right kidney was discharged through a fistula in the left loin where the ureter had been simply cut off after extirpation of a tuberculous kidney, I have modified my method, and now invariably cauterize the lumen of the distal end with a Paquelin, and then tie it with catgut. Prior to operation the cystoscope had shown, in the case just referred to, the mouth of the right ureter to be healthy; that of the left much ulcerated. By the ulcerative process the physiologic valve-action of the ureteral mouth had been completely destroyed. The urine, after having descended from the right kidney, simply ran up and out of the open lumen in the left lumbar region, principally when the patient was in a recumbent posture.

Primary total ureterectomy for tuberculosis is certainly rarely indicated. Howard A. Kelly of Baltimore, James Israel of Berlin, and a few others have reported such cases. Here it was seen during nephrectomy that the ureter was very seriously affected. Partial resection of the renal portion would have been equivalent to an incomplete operation.

In the majority of this class of cases, however, I think, the ureter will take care of itself, if the case had been correctly diagnosticated in the beginning of the disease, and then promptly subjected to nephrectomy. With the source of the trouble, *viz.*, the primarily diseased tuberculous kidney, removed, the continued reinfection of the ureter ceases, and the tuberculous process within the ureter heals. The cystoscope nicely corroborates this assumption. In the majority of cases of primary renal tuberculosis, the cystoscope shows the corresponding ureteral opening ulcerated. If the correct diagnosis be established early, and nephrectomy carried out promptly, these ulcerations around the vesical end of the ureter disappear. It is to be expected that the same will happen with tuberculous infiltrations or ulcerations farther up within the canal; in other words, that the process within the ureter heals.

In a very interesting case of this class I saw the formerly much-diseased ureteral mouth fully restored four months after nephrectomy. The patient, a woman of forty-six years, had been sick with urinary symptoms not quite a year. She is absolutely cured and well up to date.[1]

It seems to me that the cystoscope might often furnish the best means for determining the indication for secondary ureterectomy in tuberculous cases. If these ulcerations of the ureteral mouth and in its immediate neighborhood persist after *an early nephrectomy* on that side, we may conclude that the tuberculous process within the ureter has no tendency to heal.

[1] In one case, I learned lately, the lumbar wound broke open again about eight months after nephrectomy and necessitated the removal of the upper portion of the ureter.

[1] Medical News, May 1, 1897.

On pressing upon the hypochondriac region during cystoscopy, we shall then probably also observe the entrance of pus from the ureter into the bladder. I think that we can rely on these cystoscopic facts.

Another indication for secondary ureterectomy in tuberculous cases may arise if the original wound, which had thoroughly healed at first, breaks open again and a sinus establishes itself.

A few months ago a lady was sent to me by one of the leading surgeons of this city with the request that I establish the presence or absence of a tuberculous process in a ureter which had been left behind after nephrectomy. The operation had been done by a surgeon outside of New York, for—it was stated—tuberculosis of the left kidney associated with stone. Lately the lumbar wound, which had at first closed firmly, had reopened and the lumbar fistula annoyed the patient. Her physician at home had diagnosed: Continuation of the tuberculous disease within the ureter of the formerly affected side. He advised immediate removal of the whole canal, an operation which was much dreaded by the patient, and for which she was for special reasons ill prepared at that particular time. Her doctor had insisted on the advisability of immediate interference, however, and sent her to New York for that purpose. The questions which I was asked to solve were: Is the left ureter diseased? If so, is it tuberculous? Does the pus in the urine come from that ureter or from the right kidney? The cystoscope showed a rather healthy bladder and the left ureteral mouth not ulcerated; but a flake of pus rested in its lumen and projected into the fluid within the bladder, swaying to and fro. On pressing over the course of the left ureter from without, a few more drops of thick pus were seen to slowly enter the bladder and drop into the fundus. In view of the suppuration within the ureter, but the total absence of ulcerations around the ureteral mouth and in the bladder, in view also of the extreme rarity of the combination of the two pathologic processes in the kidney—tuberculosis and stone,[1] I expressed the opinion that the removed kidney had probably not been tuberculous, but a pyonephrotic stone kidney, and that now, perhaps, an impacted stone or a stricture of the ureter was the cause of the intra-ureteral suppuration. I thereupon advised, if the lumbar fistula should persist in annoying the patient by its discharge, to cut down on the ureter at a time convenient to the patient and remove the stone; or, if the ureter should be found more seriously diseased, or if a stricture should be the cause of the trouble, to extirpate the entire canal. On microscopic examination of the pus discharged from the lumbar sinus, done later, tubercle bacilli could not be detected, nor could their presence be demonstrated by urinary analysis. The further development of the case up to date seems to prove the correctness of my conclusions.

In none of my cases of renal tuberculosis, where the patients died months or years after nephrectomy, could the cause of death be attributed to the fact that a probably diseased ureter had been left behind. Nevertheless, the statement that the ureter of a tuberculous kidney, provided the trouble had been diagnosticated and attacked *early*, can generally be safely left behind, is not conclusive by any means. Only carefully conducted autopsies on patients who died after nephrectomy for tuberculosis, without ureterectomy having been added, will clear up this question. To-day we can say this much, however, that total extirpation of the ureter in combination with removal of a tuberculous kidney is indicated only if the tube is visibly enlarged and suppurating.

3. *Pyonephrosis and Pyonephrotic Stone Kidney.*—It was the operation performed on a case belonging to this class that induced me to write this article. I will discuss this indication for total extirpation of the ureter in the course of my statement of the history of the case.

G. H., twenty-three years of age; born in the United States, has always been perfectly well in regard to his urinary system until five years ago when, suddenly, without any apparent reason, he was seized with lumbar pain, more pronounced on the left than on the right side. A few days later a rather severe hematuria set in. Blood was found to be intimately mixed with the urine. He passed blood for six to seven weeks. After that a good deal of mucopurulent deposit was found in the urine. The hematuria never returned, but the turbidity of the urine continued. About two years ago micturition became more frequent; the patient urinated every two hours during the day, not at all during the night. The act of micturition was not accompanied with pain. There was no tenesmus. He had never passed a stone.

When first seen by me in June, 1897, he urinated four to five times during the day, with some pain at the neck of the bladder during the act of micturition; nights, but once. Of late he had noticed more sediment in his water, and occasionally pains in the left lumbar region, which traveled down toward the bladder. Before that the urine had been quite clear at times, and he had had less trouble and pain. The patient's father had died from phthisis, also his mother, and an uncle and an aunt upon his father's side. The patient himself had often had pneumonic attacks during childhood. He never had gonorrhea. During the last two years he had been at times seized with what appeared to be epileptiform attacks. The patient is a well built, rather muscular young man. On palpation both kidneys appear free from pain on pressure; prostate is sensitive, its right lateral lobe somewhat larger than the left. On massaging the same per rectum, some viscid fluid is discharged

[1] I have observed but one case in which I found an exceedingly small concretion within a tuberculous renal abscess.

through the meatus. The patient maintains that a similar discharge has been frequently observed lately after defecation. Urinary analysis shows: Urine, acid, contains ¾ per mille albumin, few blood cells, little mucus and pus, few hyaline and epithelial-studded casts, no tubercle bacilli, cells of superficial and middle layer of bladder, also groups from renal pelvis. Diagnosis based on this analysis: Hyperemia of the parenchyma of the kidneys with irritation and slight catarrh of the pelvis; possibly a more serious affection of one kidney with compensatory working of the other.

July 3d. Cystoscopy: Multiple hyperemic, slightly elevated spots, disseminated over the whole vesical mucosa. On the left lateral wall, not far from the ureteral mouth, a scarlet-red, diffusely outlined spot with some adherent mucus is detected. The right ureteral mouth shows distinct contours. In its immediate neighborhood the mucous membrane appears normal, of almost bluish-white color. Many injected vessels run from the ureteral opening into the neighboring mucosa. The right ureteral fold, as well as the interureteral bar, is very prominent and not diseased. The left ureteral mouth appears swollen and succulent, less sharply defined than the right, ragged, especially toward the median line, not greatly injected. The surrounding mucous membrane is in the same swollen condition, not ulcerated. The left ureteral fold is not as strictly defined as on the opposite side.

In view of the history of the patient, the trouble was open to the suspicion of tuberculosis. But tubercle bacilli had not been found on urinary analysis; cystoscopy revealed the left ureteral mouth to be swollen, not ulcerated. The other alternative was stone in the left kidney. On account of my pending summer vacation, the patient was for the time being put on a milk diet, increasing doses of guaiacol, and sent to the country. When seen again in the fall his condition was unchanged. The urine appeared as turbid as before. There were often pains in the region of the left, on and off also in that of the right kidney. Frequency of micturition: six to eight times during the day, once or twice during the night. Cystoscopy was repeated with the intention of catheterizing the ureters. Intravesical appearance is little changed. The right ureteral mouth and its immediate neighborhood is in the same condition as it was found four months ago; the left ureteral fold is more prominent; it projects like a small tumor into the bladder. Its mouth appears immovable during several minutes of inspection. No whirls of emerging urine are observed as on the other side. A mucous thread projects from the lumen of the same into the bladder; it sways slightly within the fluid that had been injected into the viscus previous to examination, but it is not pushed off, as is generally seen effected by the jets of intermittently descending urine. Catheterization of the ureters with Casper's instrument: It is easily accomplished on the right side where the tiny catheter is pushed up into the ureter for about one inch to an inch and a half, and 10 cc. of clear urine are collected in twenty minutes. The patient had not ingested any special amount of liquid before the examination. The left ureteral mouth is also easily entered, but the catheter cannot be introduced for any distance; about one-half inch up a distinct obstruction is encountered. On pushing the catheter from without it is seen to be bending at the ureteral opening. Separate drainage of the left kidney is impossible. As the patient had passed 250 cc. of a rather turbid urine just before the examination, this amount together with that drained from the right kidney was sent to Dr. Sondern's laboratory for examination. Report on bladder urine: Acid, specific gravity 1016, moderately marked deposit; amount of urea, 0.019 gm. in 1 cc.; trace of albumin; chlorides approximately 0.005 gm. in 1 cc.; moderate excess of phosphates; no blood; small amount of pus and mucus; some hyaline casts; no tubercle bacilli; numerous cells of the superficial and middle layers of the bladder; considerable amorphous urate deposit. Report on specimen per ureter catheter from the right kidney: Acid, specific gravity 1023; amount of urea, 0.025 gm. in 1 cc.; trace of albumin; chlorides approximately, 0.001 gm. in 1 cc.; no excess of phosphates; small amount of blood (from use of catheter); no pus, mucus, casts, or bacteria; numerous cells of ureter; considerable amount of amorphous urate deposit. Conclusions: Right kidney normal; left kidney, at least a hyperemia of the parenchyma and probably a more marked lesion, with compensating excretory action of the other kidney; with at least a catarrh of the renal pelvis and probably a moderate pyelitis; chronic cystitis.

On basis of these facts the patient was advised to enter the hospital for nephrotomy, probably nephrectomy on the left side. I expressed the view that the pyelonephritis was probably due to stone; that there also was a stricture of the left ureter near its vesical end, the result of former ulceration, or due to an impacted stone. The possibility was mentioned further that in spite of the repeated absence of tubercle bacilli in the urinary specimens the cause of the trouble might be tuberculous.

November 20th. Nephrotomy at the German Hospital. Simon's incision. Kidney large, hyperemic, with fluctuating pelvis, and dilated upper portion of the ureter. No tubercles are found on the kidney surface. The organ is easily brought in front of the lumbar incision. No stone is palpable. Aspiration of the pelvis demonstrates the presence of a slightly turbid fluid. On incising the pelvis about three ounces of the described fluid ran out. The finger introduced fails to detect a concretion. The calices are enlarged. To make things absolutely sure, the renal vessels are compressed by an assistant's fingers and the kidney is incised at its convexity and split in two halves, down into its

pelvis (section cut). There is no stone in the parenchyma either. The renal tissue appears not materially altered. The two halves are stitched together with four to five catgut sutures; the digital compression of the pedicle is then interrupted. The consequent slight oozing at the site of the incision is easily controlled by pressing some aseptic gauze on the wound for a short while.

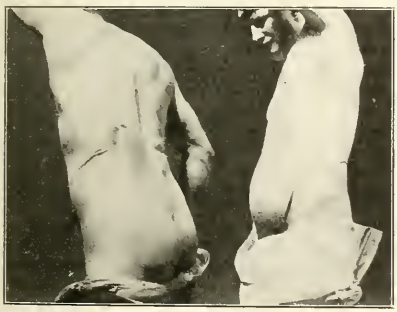
The cause of the hydro-pyonephrosis, then, was not found in the kidney itself. It had to be looked for farther down. The kidney was pushed back into its normal bed, the edges of the pyelotomy-wound were held apart with sharp retractors and the ureter explored. A flexible rubber bougie met an insurmountable resistance about six to eight inches below the pelvis. On introducing a small soft-rubber catheter, cut off transversely at its end, and throwing in sterile water with a hand-syringe, it was seen that about one to two ounces would flow down without reappearing. But on increasing the quantity of the injected fluid, suddenly the whole amount was regurgitated. The procedure was repeated to make sure of the observed phenomenon. The catheter was withdrawn from the ureter, and a long metal probe was introduced instead. It met the same firm, but soft obstruction. There was no feeling of grating. Conclusions: Stricture of the ureter with accompanying hydro-pyonephrosis. The causative factor was so far unknown. Perhaps, in view of the result of the ureteral catheterism, a stone which had traveled down, and was now impacted in the ureter near the ureteral mouth, had formerly set up an ulceration with consecutive formation of a stricture at that spot. In consideration of the comparatively good appearance of the renal parenchyma, at least macroscopically, I could not at the moment make up my mind to remove the kidney. Accordingly the pelvis was drained, the remaining wound tamponed with aseptic gauze, and the patient brought to bed. On the following day I explained the condition to the young man. I stated that I could try to resect the ureteral stricture and perform a uretero-ureterostomy, and thus succeed probably in saving the kidney; but that I could not promise a cure. On the other hand, the treatment might be considerably shortened by removing the kidney, an operation which could still be easily accomplished, and was justifiable, as we knew from the previous separate drainage that its fellow was present and healthy.

The patient decided to have the left kidney extirpated. On November 24th the gauze was removed from the wound, a strong clamp applied to the renal vessels with ureter and the kidney cut off. The wound was sutured at its ends, otherwise left open and drained with strips of sterile gauze. The clamp was removed after forty-eight hours. Recovery was uninterrupted. Early in January, 1898, the patient was discharged with his wound healed and much improved in every respect. I then lost sight of him.

Fifteen months later, in March, 1899, my friend, Dr. Herm. Goldenberg, called on me to inquire what kind of an operation I had performed on G. H. The young man had come to his department in the dispensary of the Mt. Sinai Hospital, complaining of pain in both lumbar regions, frequent turbidity of urine, and general malaise. Separate collection of the urine with Harris' segregator on two occasions had shown the descent of clear urine from the right side and about one to two ounces of turbid, purulent urine from the left. This result was inexplicable, inasmuch as the patient maintained that his left kidney had been removed. In answer to the inquiry, I explained that the left kidney had been removed, but that its strictured ureter had been left behind. I called attention to the possible inaccuracy of the result obtained with Harris' treatment. The latter was at that time on trial in New York in the hands of many colleagues. The doctor promised to repeat the examination for a third time. If the same misleading observation should be made, we agreed that the bladder should first be thoroughly flushed until the water returned clear; a specimen of this clear fluid should be put aside. Then the same amount of clear water should be thrown into the bladder, the catheter, plugged, left in place, and massage performed for a short while along the diseased left ureter. If the water in the bladder should become turbid, it would be proven that the site of the suppuration was within the left ureter. A third trial with Harris' instrument again allowed about 10 cc. of a turbid urine to run from the left of the intravesical watershed. The other experiment gave a positive result. Having later satisfied myself as to the correctness of the massage-test over the left ureter, the indication for ureterectomy was clearly established. On March 18th it was done at the German Hospital, with the incision as devised by James Israel of Berlin. The cut was made through the abdominal wall from the tip of the eleventh rib toward a place corresponding to the middle of Poupart's ligament. The ureter was found to be about the size of the thumb, soft, fluctuating, and covered with a dense network of small blood-vessels. After careful dissection an additional incision was made at the upper end of the wound, parallel to the twelfth rib, into the scar that had resulted from the former nephrectomy, and the wound at its lower end continued to the border of the left rectus muscle. By turning the patient on his right side and placing him in a Trendelenburg posture of various degrees, I well succeeded in exposing the entire canal down to the bladder without ever entering its cavity. It was clearly visible from without that there was a tight stricture at the junction of about the middle and lower thirds of the ureter. When about to tie off the lower portion at its entrance into the vesical wall, a stone of about the size of a large pea was found firmly wedged in the ureter, just above the ureteral mouth. After some efforts

it was successfully dislodged and pressed into the ureter toward the lower aspect of the stricture. Then the upper and lower ends of the ureter were tied off with strong catgut, and the whole organ removed by cutting it off between these ligatures and a clamp, which had been applied about half an inch away from each ligature. In order to catch a possibly outflowing drop of the infected contents of the ureter, aseptic gauze had been pushed below the organ, near the bladder. I thus succeeded in keeping the large retroperitoneal wound absolutely aseptic. The lumen of each stump was then cauterized with the Paquelin, a strip of sterilized gauze run down to them, and the entire abdominal wound carefully closed layer by layer with continuous catgut sutures. The patient made a perfect and uninterrupted recovery. To-day, ten months after the operation, his abdominal wall is firm everywhere; there is no tendency to hernia. Fig. 1

FIG. 1.



Extirpation of Ureter.

shows the extent and present appearance of the scar. The specimen, when cut open, presented a very narrow stricture at the junction of the middle and lower thirds of the canal, as stated. The part above as well as below it was much dilated (see Fig. 2). The stone had a number of sharp projections all over its circumference. They had, no doubt, caused its firm lodgement within the vesicle end of the ureter, just within its narrowest spot, the mouth.

With these pathologic specimens at hand, the history of the case is easily explained: Five years ago this stone entered the ureter, producing pain and the hematuria. At its entrance into the small pelvis it was arrested, causing the ulceration, followed by stricture. Later the stone itself traveled farther down, but was again held up right in front of the ureteral mouth on account of its irregular surface. This second stricture in the course of the ureter, represented by the stone, caused the dilatation of its lower third. That it was this one stone only that gave rise to the many years of sickness is proven by the fact that the patient at no time had symptoms pointing to the presence of a vesical stone, nor did he ever pass any. To-day the patient voids perfectly clear urine at normal intervals. His left side never gives him trouble; at times he experiences pain in the right kidney. Perhaps nephrolithiasis, so often found bilateral, is now developing on his right side(?). He is long back at work, but often annoyed by his epileptic seizures.

This case nicely illustrates what an amount of mischief can be produced by a single renal calculus which cannot pass the ureter. It also shows the necessity of carefully testing the patency of the lower portion of the ureter when performing uretero-ureterostomy for stricture. Had my patient consented to this conservative operation, we probably might have saved his kidney; yet, had I then omitted to satisfy myself as to the rather improbable presence of a

FIG. 2.

a. Extirpated ureter showing tight stricture at junction of middle and lower third, with marked dilatation above and below. *b*. Calculus.

second obstruction farther down, even the successful restoration of the ureteral lumen would have been a failure functionally. On the other hand, it would probably not have been difficult, at the time of such an operation, to mobilize a stone lodged within the vesical end of the ureter, and to push it up in order to be extracted through the ureteral incision before the canal was again closed.

The case further demonstrates the necessity of always testing the patency of the ureter when performing nephrotomy and nephrectomy. By doing so a stricture will be definitely diagnosticated and located. If a grating is felt at the point of resistance, the presence of a stone lodged within the ureter is demonstrated. If the stone can be reached from the lumbar wound, the surgeon ought to try and push it up and extract it. If, however, the calculus is in the lower end of the ureter, the organ ought to be exposed extraperitoneally at once, provided the patient's condition permits of such a procedure. If it does not,

it must probably be done later to avoid further trouble. In a case of nephrectomy for pyonephrotic stone kidney I lately succeeded in nicely pushing up and extracting two irregular stones from the upper part of the ureter. Free irrigation downward into the bladder proved afterward that the canal was unobstructed farther down. If a ureter is filled with a great number of calculi, it is best to excise the entire canal.

I do not believe that a stricture in the ureter without the presence of the stone, whose passage originally caused the stricture, will often necessitate the extirpation of the ureter after the kidney has been removed. It is rarely so tight as to prevent the small amount of mucus discharged above from passing into the bladder. If diagnosticated during nephrectomy we ought not to tie and canterize the ureteral stump, but rather leave the ureter open and stitch it into the lumbar wound. With proper drainage of the upper part of the ureter into the lumbar wound and, if necessary, with irrigation and dilatation of the ureteral stricture from this wound, the ureter has a better chance to heal.

Since writing this article I have done a second total extirpation of the ureter on a man, thirty-seven years of age, who had his left kidney extirpated by another surgeon for what seems to have been a pyonephrosis, almost four and a half years ago. After this his general health improved, but not the local trouble. Four months later his bladder was drained through the perineum for a number of weeks by the same surgeon; no improvement. One year later suprapubic cystotomy was done, this time in another hospital, without, however, improving his condition. A fistula remained at the site of the incision. Lately he has come under my care. On examination I felt a hard cord in the course of the left ureter, very painful on pressure. A valve-like obstruction at the neck of the bladder prevented the entrance of an instrument, even of small size. Vesical irrigation and cystoscopy were, therefore, impossible. With the view of making as distinct a diagnosis as was possible under the circumstances, I made him pass some urine. The same was turbid but odorless. Then I massaged the left groin downward. The urine then voided was entirely different in color, contained much more pus, and was very offensive. The diagnosis of chronic suppurative ureteritis was established beyond a doubt. On January 4, 1900, I extirpated the diseased ureter. The operation proved to be extremely difficult on account of the old and very firm adhesions around the very much enlarged and soft-walled canal, which had been cut off pretty far below the renal pelvis at the time of the first nephrectomy. I succeeded, however, in removing the entire ureter down to its entrance into the bladder. At this latter spot it was strictured, but did not contain a stone. The patient has made a good recovery and will soon leave the hospital.

By making it a rule always to test the patency of the ureter down into the bladder when doing a nephrotomy or a nephrectomy, and then, according to the result of this examination, adding, immediately or later, the necessary treatment of or operation on the ureter, many a kidney will be saved from extirpation and much trouble be spared to our patients.

MEDICAL PROGRESS.

The Cecum and Its Appendix.—G. Perondini (*Revue de Chirurgie,* August, 1900) gives the result of extended observation on the anatomical relations existing between the cecum and the appendix; he finds that in eighty-three per cent. of the cases the cecum is situated in the lower part of the right iliac fossa; next in frequency he finds it located in the middle of the iliac fossa or in the pelvic fossa or in the umbilical region or in the lumbar fossa. The direction of the axis is usually obliquely to the right, upward and backward; in two cases it was transverse, while in three it was vertical; the serous covering was complete in seventy-five per cent. of the cases examined; its length is usually 6 centimeters and its width 3 centimeters. The appendix was in most cases cylindrical, vertical, and within the cecum; in ten cases it was retrocecal; the average length of the appendix was found to be 7.6 centimeters, while the breadth averaged 5 millimeters.

Radical Treatment of Tubercular Testis.—A. Moschowitz (*Med. Rec.,* September 15, 1900) states that it has not yet been definitely decided whether or not there can be a primary tuberculosis of the genital tract without the coexistence of a tuberculous focus in some other part of the body; yet we not infrequently see patients with a tubercular nodule in the epididymis, who give no other tubercular symptom. The danger of such a nodule lies in its power to infect the entire genito-urinary tract, the tubercle bacilli being carried by the seminal secretion into the corresponding vas deferens, infecting first its scrotal, then its inguinal and abdominal portions, until the entire vas deferens up to the seminal vesicles is involved; then the seminal vesicles are infected and, finally, the corresponding lobe of the prostate is involved. Bearing these facts in mind, it is evident that simple castration is not radical enough to check the ravages of the disease; hence the following treatment is advised. Castration should be performed by the usual method and through the usual scroto-inguinal incision with the exception that the vas deferens is primarily not divided at the level of the vessels, but is carefully isolated from the other structures of the spermatic cord, and left in connection with the testicle; then as much of the vas deferens is pulled out of the inguinal canal as can be done without running the danger of tearing it off. After placing a ligature around it, it is divided and the proximal end is carefully seared with a Paquelin cautery, so that in the subsequent ma-

nipulation no opportunity shall be given for any exuded material to infect the channel of the vas deferens between the peritoneum and the bladder; after removal of the testicle the external incision is closed with or without drainage. The patient is then placed in the lithotomy position; a sound is introduced into the bladder to serve as a guide, and a curved incision is made in front of the anus, extending from one tuberosity of the ischium to the other—the so-called prerectal incision of Zuckerkandl, or, more preferably, Kocher's "pointed arch" incision; after division of the superficial and deep perineal fascia, and of the tendinous union between the bulbocavernosus muscle and the external sphincter of the anus, the urethra being held to the front by a blunt retractor, the space between the rectum and urethra is deepened by blunt dissection, until the levator ani, or more particularly its anterior portion—the levator prostatæ—is reached. This is then divided by a pair of scissors; the divided muscle retracts, and the prostate and diseased seminal vesicles are reached by the palpating finger; the finger of the left hand is introduced into the rectum and hooked over the upper border of the prostrate; traction is exerted and it is surprising how much of the prostate and seminal vesicles can thus be brought into view; should this, however, be impossible on account of adhesions, the seminal vesicle may be grasped by a clamp and gentle traction made to liberate it further; proceeding in this manner the entire unruptured seminal vesicle and the remaining portion of the intra-abdominal part of the vas deferens are brought into view. That the entire vas deferens is being extirpated can be recognized by the attached ligature and the seared surface. The seminal vesicle and vas deferens are by this time attached only by the ejaculatory duct which can be readily cut off; tamponade of the wound and possibly the insertion of one or two sutures into each angle of the perineal incision terminate the operation.

Osteoplastic Amputation of Long Bones.—Z. Samfirescu (*Revue de Chirurgie,* August, 1900) advocates the use of his method in cases of amputations in the continuity of the long bones of the extremities; this method consists in the formation of an osteoperiosteal flap, applied to the cut surface of the amputated bone; this gives a smooth stump covered over with periosteum and one most serviceable for the adaptation of an artificial limb. By this method the amputated bone and its diaphyseal segment unite just as soft tissues do, thus giving strength and solidity to the limb, preventing the growth of bone after amputation, and obviating the sensitive stump so often seen after the old method of amputation. While the operative technic is elaborate and consumes more time (forty to forty-five minutes) than is usually required in amputations, the author believes that subsequent permanent advantages derived from such a stump compensate for the time taken up by the operation.

Cancer of the Breast.—S. Keith (*Lancet,* August 18, 1900) says that there are but three questions of interest to both lay and professional minds, *viz.,* is it increasing; is it hereditary, and is it curable? In regard to the first two questions there is still much ground for doubt; the third question, he believes, can be answered more positively and affirmatively, yet he considers "cure" as an indefinite term unless the number of years after operative procedure is stated. Three years after operation without a recurrence of the cancer is in his experience too short a time-limit to determine permanency of cure. The removal of the breast and axillary glands is not accompanied by any serious risk; the removal of the superficial fat of the breast is as important as the removal of the pectoral muscles, as the lymphatics pass into the superficial fat. Halsted's operation he believes to be too extensive for weak patients.

Pneumonotomy with Resection of the Ribs.—M. Christovitch (*Revue de Chirurgie,* July, 1900) narrates the case of a man, accidentally wounded in the lung by a bullet, which entered at the level of the third left intercostal space. As no mark of exit could be found, it was concluded that the bullet had lodged in the lung. A simple antiseptic dressing was applied; three days later the man gave symptoms of pleural effusion, with considerable rise of temperature, until the sixth day, when his condition became so critical that an operation seemed indicated; puncture in the seventh intercostal space revealed the presence of purulent blood-tinged fluid, all of which was removed by a free intercostal incision; a small portion of the chest-wall having been resected, the bullet was felt in the lung tissue. A V-shaped flap was made over the upper part of the lung; the lung was incised and the bullet was extracted together with small foci of gangrenous lung tissue; the hemorrhage, which was slight, was controlled by gauze tampons, and free drainage was secured by the insertion of two medium-sized drainage-tubes. After an uneventful convalescence of seven weeks the patient left the hospital cured.

Kahler's Disease.—D. Allocco (*La Riforma Medica,* June 19, 1900) records the case of a man, a shoemaker, aged seventy-five years, whose previous personal and family history were negative until nine months previously, when he began to notice pain over the sternum at a spot corresponding to the pressure caused by use of a shoemaker's iron-shoe. Later a painful swelling, the size of a small orange, developed over the sternum, between the second and fifth rib, extending beyond the right and left edge of the sternum; this swelling had a pulsation synchronous with the heart's beat; over it the heart sounds were readily heard, the second sound being markedly accentuated; pulse was regular, strong, and synchronous with pulsation of the sternal tumor. Two months later pain and

swelling appeared in the left upper extremity, soon followed by a spontaneous fracture at the juncture of the upper and middle third of the humerus; a few weeks later painful nodules appeared on the ribs, having the same general appearance as that on the sternum which had become larger in volume; the skin over the sternal tumor was livid and appeared necrotic in spots; a Pravaz needle inserted into the sternal mass proved it to be solid. Soon fracture of the ribs occurred at the site of the nodules already described, followed now by spontaneous fracture involving the right humerus. The patient's general condition had meantime grown steadily worse. A tumor soon appeared at the crest of the left iliac bone; this mass grew rapidly in size; on palpation a disc of bone could be distinguished free in the mass; except for pain in the bones on passive movement, there were no other marked symptoms. The anemia and cachexia increased gradually, until at the end of the eleventh month from the beginning of the disease the patient died. Autopsy revealed the presence of uniform bone changes which consisted principally of a rarefaction of the medulla of the bones; although in life the vertebræ had given no clinical signs, they were found to be the seat of the same process as was found in the sternum; the heart was anemic and dilated; the liver diminished in size, while the spleen was somewhat enlarged; the kidneys were congested. The interest in the case lies in the question of a diagnosis in life; at first it appeared as though the sternal swelling were an aneurismal tumor involving the arch of the aorta; not until other osseous symptoms arose was the correct diagnosis possible. Whenever there is a history of such bone swelling and fracture one may expect to find *a marked and persistent albuminuria;* these symptoms, together with the progressive nature of the disease, characterize Kahler's disease.

Massage in Peri-Articular Fractures.—G. Woolsey (*Annals of Surgery*, September, 1900), acting on the theory of Championnière that immobilization of a fracture relieves only the primary pain due to the movements of the fractured ends on one another, allowing or favoring the secondary pain due to swelling of the surrounding parts that it imperfectly restores the original form of the part, especially in fractures near joints, when the swelling may produce the deformity; that it does not favor the repair of bone or the restoration of function, but, on the contrary, causes scantiness of callus, sometimes resulting in delayed union or in stiffness of the neighboring joints or atrophy of the muscles of the limb has found that *massage* in fractures, peri-articular ones especially, gives striking results, shortening the time of repair by one-third, and of functional use by one-half or more, avoiding subsequent stiff joints and atrophied muscles. Splints or retentive apparatus should be employed between the applications of massage, as it gives a greater sense of security to the patient, as well as to the surgeon, to feel that in the interval the displacement of fragments is not possible; in Pott's fracture, where there is a strong tendency to a posterior displacement or lateral mobility, one may have to forego massage and leave the foot in a plaster splint. Massage is usually begun about the third day after the receipt of the injury, although it may be employed in various cases from the first or the seventeenth day; it must be begun carefully and gradually increased. As far as functional result is concerned, it is better to put the fracture up in plaster first and massage afterward, than the reverse; in a series of forty-seven hospital cases, the date of first being allowed up out of bed, after Pott's fracture, averaged nineteen days; care should be taken not to allow the patient to walk too soon or too much without support. In fracture of the patella there is no treatment which yields better results as to union and function than massage combined with elastic compression at first and passive motion later. Massage is equally valuable in fractures into or near the elbow-joint, also in Colles' fracture; the latter may be treated without splints from the first, with only a bandage around the wrist; it is also applicable in a limited number of fractures of the shaft of the long bone, where there is no great amount of deformity. Massage is contraindicated in compound fractures; in fracture with large blebs or a projecting fragment, great mobility or a tendency of the deformity to be reproduced and in certain fractures of the long bones. The application of massage and passive motion is easy; it relieves pain and swelling; hastens callus formation and solidification, and prevents atrophy of the muscles and stiffness of the joints and tendons. Particular attention should be paid to the position of the limb, by carefully reducing any deformity and keeping it reduced during massage and between the periods of massage, when the limb is in a splint. If this is not possible from the outset, after a preliminary massage, a plaster splint should be applied and kept on for from eight to fourteen days, and then massage commenced; the result in these cases is better as far as position is concerned, equally good functionally, and nearly, if not quite, as quickly obtained as when massage is employed from the first; if, after massaging for some time, the position is found to be imperfect, or if, after three weeks, quite firm union has not taken place, use a plaster splint for eight to fourteen days, although the functional result may be delayed thereby.

"Gun-Stock" Deformity in Fracture of the Humerus.—L. A. Stimson (*Annals of Surgery*, September, 1900) notes that fracture of the lower end of the humerus in some of its forms is not infrequently followed, especially in the young, by a conspicuous deformity of the limb known as cubitus varus or "gun-stock" deformity, which consists in marked permanent adduction of the

forearm which is most apparent when the elbow is in full extension; the most marked clinical feature is the apparently abrupt movement made by the forearm toward the ulnar side as the limb approaches full extension, and the peculiarly ungraceful appearance of the limb in this position; flexion, extension, and rotation are usually normal; the elbow viewed from behind shows the olecranon prominent and slightly displaced toward the inner side; flattening of the inner side of the elbow and fulness of the outer side, on flexion at a right angle, with apparent enlargement of the external condyle below and behind. It seems fair to conclude from cases observed that the common anatomical cause of cubitus varus is not ascent of the internal or descent of the external condyle after fracture extending into the joint, but, on the contrary, it is an angular displacement of the entire lower end of the bone after a supracondyloid fracture, or of its lower portion after a fracture, which is practically a partial separation of the cartilaginous epiphysis, especially at its outer side; the latter form of fracture seems to be possible only at an early age, not over ten or twelve years. Recognition of the displacement ought to be easy by attention to the level of the external epicondyle and head of the radius as compared with that of the internal epicondyle: the lower end of the supinator ridge must not be mistaken for the external epicondyle. Correction of the displacement could probably be easily made by pressure upward and outward against the olecranon in rectangular flexion of the joint, or abduction of the fully extended forearm, and maintenance of the latter position for a week or two, would probably be the surest means of preventing recurrence; but it should be combined with confinement to the bed; full flexion of the joint—so uniformly recommended in the treatment of all forms of fracture in this locality—could not be trusted to correct the displacement, or prevent recurrence, because in all patients seen he has found free flexion of the joint to be possible. As the deformity does not prevent the attitude, the attitude cannot prevent the deformity. If the convenient attitude of flexion at a right angle is chosen, and especially if the fracture is supracondyloid, pressure upward against the olecranon by a supporting sling must be carefully avoided, because such pressure would be transmitted to the inner half of the fragment, and would tend to produce the deviation, which we seek to avoid; the sling should take the weight of the limb at the wrist. In the other, the lower and the common form of the fracture, the rectangular position might be safely taken, if incasement in plaster of Paris was used, and the upper portion of the dressing carried over the top of the shoulder so as to prevent its descent, which would permit or perhaps even produce recurrence of the displacement.

The X-Rays and Thoracic Tumors.—E. Gebauer (*Deutsche med. Wochenschr.*, August 30, 1900) reports a case in which the history and physical signs pointed toward either pulmonary tuberculosis with great infiltration of the glands, a mediastinal new growth or aneurism of the aorta. In favor of the first were phthisical signs at the right apex, a characteristic temperature and swelling of the glands, while against it was the absence of tubercle bacilli. The presence of external dulness and Oliver's sign seemed to point toward aneurism, while the dulness, cachexia and dysphagia indicated a tumor. On examination with the fluoroscope a large pulsating mass was seen above the heart and the diagnosis of aneurism seemed confirmed. The autopsy, however, revealed extensive malignant disease of the esophagus which had invaded the lungs and formed a large mass which received and transmitted the cardiac impulse. The case is interesting as showing the caution necessary in drawing conclusions from radiographic pictures.

Queirolo's Method for Determining Stomach Boundaries.—For the accurate projection of the stomach boundaries on the abdominal surface it is usually considered necessary to inflate the stomach either with CO_2 gas or by direct insufflation of air. By means of a specially devised instrument an attempt has been made to secure greater accuracy without resorting to these troublesome maneuvers, and Edel and Volhard (*Deutsche med. Wochenschr.*, August 30, 1900) have conducted a series of comparative observations in order to determine the relative merits of the two methods. The apparatus consists of an ordinary stomach-tube whose lower end bears a small balloon, while at the other extremity are two small tubes, one connecting with a Marey registering drum, while the other is free and serves for the inflation of the balloon. After introduction this latter is moderately distended with air and, on percussion of the abdomen, as soon as the gastric limits are reached, an impulse is transmitted to the index of the registering apparatus. For the proper working of the contrivance it is essential that a certain amount of air tension be present within the stomach, and then percussion over it causes a sufficient compression of the bulb to affect the telltale. It was found that the method was accurate and gave clear-cut results but that it possessed no appreciable advantages over the older means of diagnosis.

Diphtheria and Antitoxin.—John Leverett (*Phila. Med. Jour.*, September 15, 1900) gives an interesting report of nine cases of diphtheria and calls attention to some points which he has learned about antitoxin. In Cases I. and II. 1000 units of antitoxin were injected as soon as the report was received announcing the presence in the culture of the Klebs-Löffler bacilli. This was about twelve hours after the culture was obtained. The membrane in these two cases disappeared in forty-eight hours and thirty-six hours, respectively, and the patients felt well in

a few days, but cultures showed that the bacilli were present until the thirteenth day. Of the next five cases, which occurred in one family, two died. One of these was a case of laryngeal diphtheria which, in spite of the fact that the patient received 1000 units of antitoxin as soon as the report showed the presence of the Klebs-Löffler bacilli and 2000 units the following day, got worse, although the breathing was easier, and died. The writer thinks that laryngeal diphtheria is so far advanced when it is usually diagnosed that antitoxin is apt to be useless. In the second of these two fatal cases antitoxin was not given, as the disease was so far advanced when seen. The membrane peeled off, however, in due time, and the patient seemed about to get well, when her heart got weak and she died of heart failure. In the three other cases in this family antitoxin was injected as soon as the membrane was noticed, with the result in each case that the membrane promptly peeled off and the patients rapidly recovered. The bacteria persisted in the patients' throats for about sixteen days. The eighth case occurred in a little girl who was accustomed to frequent sore throat. A culture showed Klebs-Löffler bacilli, but antitoxin was not used because the case was so far advanced when the diagnosis was made, and because the family were so firmly convinced that she had only an ordinary sore throat that the writer knew that if antitoxin were given and the patient died, the antitoxin would be considered the cause of death. The membrane disappeared but the patient died of heart failure. The ninth case, that of a baby, received 1000 units of antitoxin as soon as the bacilli were reported and was well and playing about in three days. Antitoxin should always be used in the first few days of the disease before the poison has been thoroughly absorbed into the system, as was the case in two cases here reported which resulted fatally. One important point emphasized by these cases is that the bacilli persist after the patient is clinically well if the case has been treated by antitoxin. This is important as regards the spread of the disease. The writer uses an ordinary hypodermic syringe and says that the antitoxin is best injected under the skin of the abdomen or loins. With a 30-minim syringe the needle will have to be inserted four times to inject 1000 units standard. There will be less pain if injected slowly.

Mental Disturbances After Eye Operations.—Inasmuch as delirium following the extraction of cataract is of not rare occurrence and the textbooks do not give much attention to the subject, W. C. Campbell (*Phila. Med. Jour.*, September 15, 1900) reports 2 cases occurring in his own practice and 22 other cases which have come to his notice, with a view to ascertaining what the causation of the delirium might be and what are the best measures to adopt for its prevention and relief. The removal of cataract is the operation on the eye which is most frequently followed by disturbances of the mind. This disturbance generally consists of delirium which appears usually upon the evening of the third day after the operation and continues from a few days to a week, according to the treatment. This mental disarrangement rarely occurs in the young, but usually in those of advanced age, especially those who are predisposed by heredity, alcoholism, etc., to mental aberration. Toward the evening of the second or third day after the operation the patients become restless, want to get out of bed, and try to tear the dressings from the eyes. Rapid and violent delirium soon appears and often ideas of persecution are present. Although these symptoms are more marked at night, they are not entirely absent during the day. After a few days the delirium subsides without leaving any permanent mental aberration. There is seldom any complaint of pain in the eye, and any rise of temperature is accidental and not constant. These symptoms may vary, but the above is the condition in most cases. The writer discusses briefly the various theories which have been set forth by different observers as to the cause of the delirium. In the 24 cases here reported the delirium appeared eleven times after simple extraction; eight times after the combined operation; three times after iridectomy for glaucoma, and twice in traumatic cases. The ages of the patients varied from fifty to over eighty years. The traumatic cases were much younger. In 2 cases the delirium appeared during the first twenty-four hours after the operation; in 8 cases on the second day; in 6 cases on the third day; and in 2 cases on the fourth day. Both eyes were bandaged after the operation in every case, but in 9 cases the dressing was removed from the unoperated eye as soon as the delirium began, but without any relief to the mental condition. In 9 cases there was no tendency to mental aberration, but in 2 cases such a tendency was well-marked. The character of the delirium was the same in all the cases, beginning with a restlessness which rapidly developed into active delirium with hallucinations and ideas of persecution. All cases recovered their mental equilibrium. The writer believes that the facts presented by these cases dispose of most of the theories advanced by different observers as to the causation of the delirium, and thinks that the cause is largely psychic, due to the preoccupation of the patient prior to and after the operation, and the suspense and tension under which he must be. As to treatment, Campbell gives chloral and bromides freely and repeatedly, beginning at the first sign of the appearance of the delirium.

Ichthoform.—H. Goldmann (*Centralbl. f. gesammt. Therap.*, September, 1900) speaks of ichthoform as being to a high degree bactericidal, antifermentative and deodorizing and therefore considers it well adapted to replace iodoform, especially since it lacks the odor and the poisonous qualities of the latter. Internally it is of use in all conditions of the digestive tract

depending on atony or altered secretions and also in intestinal tuberculosis. On wounds it stimulates granulations in a remarkable way, in addition to exerting an antiseptic action which exceeds that of iodoform. An advantage not to be disregarded lies in the fact that neither kidneys nor nervous system are in the least irritated even after continued use.

Cause of Migraine.—J. Deye (*Klin. therap. Woch.*, September 2, 1900) has examined many cadavers with the view to finding some anatomical peculiarity to explain the symptoms of disturbed function of the ophthalmic nerve in migraine, and advances the following novel explanation which conclusively disproves the presence of a true paralysis: The ophthalmic nerve stands in intimate relation with the carotid artery in the cavernous sinus, while between the sinuses of both sides is placed the hypophysis, the lateral borders of which are in close contact with cavernous tissue. In case of cerebral congestion from intense mental activity or other cause, the cavernous tissue will tend to swell with consequent compression of the afferent vessels of the hypophysis. This in turn will lead to enlargement of the hypophysis, and, in case the space between the two cavernous sinuses should be narrow, compression of the ophthalmic nerve between carotid and dura. Anything depleting the brain of blood, such as sleep, will diminish the pressure and hence relieve the migraine. The author has found an abnormally narrow intercavernous space in a certain percentage which coincided with the number of migraine cases among the population.

Spinal Anesthesia.—A. Bier (*Münch. med. Woch.*, September 4, 1900) has used spinal injections of cocaine to replace general anesthesia for several months, but finds that untoward aftereffects occurred rather too frequently to be compatible with the general use of this method. The vomiting, headache, vertigo and weakness, which often persisted for days, he is however inclined to ascribe not to the cocaine but to the efflux of cerebrospinal liquor which occurs, and, in some cases, to idiosyncrasy. The indiscriminate use of large doses is earnestly warned against since extended experiments on animals have still to be made to determine exactly the limits of safety. To make spinal anesthesia an ideal narcosis, cocaine should not manifest more poisonous symptoms than if injected anywhere else—a state of affairs which, with the method at present employed, does not as yet obtain; it should be as efficient for operations on the upper as on the lower part of the body; and, lastly, experiments should be made with other drugs with a view to replacing cocaine.

Hour-Glass Stomach.—F. S. Watson (*Annals of Surgery*, July, 1900) gives a *résumé* of this condition which presents itself in two forms, the congenital and the acquired. The former is characterized by the symmetrical contour of the constriction and by the absence of pathological processes immediately connected with it, the latter being the most conclusive, and as it seems to the writer, the only positive evidence of its congenital nature. The acquired form is characterized by the presence of pathological processes in immediate relation with the construction; these are in a large majority of cases the cicatrices of former gastric ulcers, or the adhesions originating from these conditions and attaching the stomach to some adjacent structure; less frequently the hour-glass deformity is produced by adhesions originating from inflammatory processes outside the stomach and involving it secondarily; in a few instances, cancerous disease of a neighboring organ has brought it about, and the contraction has been caused by the cicatricial deposit following the ingestion of caustic chemicals. The constriction usually is located at the middle of the stomach, or at the junction of the middle and lower thirds. This condition is more frequent in men than in women and usually occurs between the thirtieth and sixtieth year. The symptoms in general are the same as those seen in connection with benign stenosis of the pylorus; in the congenital form, the symptoms may be slight or not appreciable until later on in life, usually in advanced age. The following facts may help us in differentiating this condition from stenosis of the pylorus. If fluid be injected into the stomach, instead of returning through the irrigating tube, it may seem suddenly to disappear, as though it had flowed through a large hole; again, when the stomach has apparently been washed quite clean, there may suddenly be returned through the tube a quantity of partially digested food, presumably food regurgitated from the second half of the stomach back into the first; or, when fluid is injected into the stomach, the left side of the epigastrium may become distended, and then a moment or two later, this swelling may subside, while at the same moment there will appear an enlargement of the right side of the epigastrium, these changes being accompanied by a gurgling sound such as is made by air and liquid being forced through a narrow channel; finally, we may note a persistence of the splashing sound on succussion after lavage. Vomiting is the most constant sign, almost always following at once or very soon after taking food. Loss of weight is almost invariable; hematemesis is not likely to occur unless gastric ulcer has previously existed; free hydrochloric acid is probably present in most cases; gastric pain is a frequent symptom, often severe, and almost always provoked by food. The treatment of this hour-glass condition of the stomach is purely surgical; gastro-anastomosis being the most serviceable, allowing large communicating openings between the two portions of the stomach to be made, thereby avoiding the formation of cicatricial areas, utilizing the digestive and motor functions of the pyloric half, and preserving the natural outlet of the stomach undisturbed.

THERAPEUTIC HINTS.

Removal of the Uvula.—Lennox Browne (*Jour. of Laryngology*) says that not only does a long, relaxed uvula predispose to pulmonary disease, but it may be the direct inciter of the chest symptoms. He instances the case of a physician, who, with irritable cough, constant pain in the left infrascapular region, and loss of flesh and strength, was pronounced a consumptive by two eminent diagnosticians. Following the removal of his uvula he quickly regained his health, and for twenty-five years carried on an active practice without any sign of diseased lungs.

Acne.—In this condition, in spite of the greasiness of the skin, F. H. Barendt (*Liverpool Medico-Chir. Jour.*, No. 38) stops the use of soap and water. Instead he orders hot oil as a wash on the principle that this easily dissolves solid fatty matter. By this means comedones are dissolved and the skin softened in preparation for the application of sulphur. Lanolin, as it approximates the composition of human fat, is a valuable base; it should, however, always be mixed with oil, vaseline, or benzoated lard. In prescribing an ointment for acne, give explicit directions and set a time during which it is to be rubbed in.

Feeding in Gastric Ulcer.—Rest in bed demands less food and less digestive work. The diet should be fluid with or without completely digestible solids in fine subdivision, and it should be neither very cold nor very hot. Milk, if well borne, is the main source of nourishment. It is unirritating, combines rapidly the secreted hydrochloric acid, does not excite much secretion, and is easily evacuated by the stomach. Not more than two quarts should be taken in a day, and one glass should constitute a feeding. It should be slowly sipped at first, and, to avoid accumulation and distention of the stomach, the intervals should be from two to four hours, that is, long enough for the stomach to empty itself. One or two tablespoonfuls of milk-sugar may be added to the first glass each morning as a nutritive and laxative. After the pain and vomiting subside, a small quantity of a well-cooked wheat preparation may be added twice a day, and later meat broth with a beaten egg stirred in may replace one or more of the milk feedings. Tender meats, cereals, and butter are next added, then vegetables. The patient should be kept for several months on a mixed, non-irritating diet, and must for a long time avoid acid fruits, alcoholic drinks, rich foods, condiments, and sweets. Rectal feeding may well supplement the milk diet, and must be used exclusively if the stomach is intolerant or there is hemorrhage or a fresh perforation.—(*Van Valzah and Nisbet in "Diseases of the Stomach."*)

Chronic Constipation.—One of A. L. Loomis' favorite prescriptions was:

℞ Ext. Nuc. Vomicæ..... gr. xij
Ext. Aloes .....
Ext. Colchici Aceticæ.....
Calomel .....
Ipecac ..... aa gr. xx.

M. et div. in pil. No. XX. Sig. One at night.

Cholecystitis in Typhoid.—Da Costa treated this by calomel in small doses frequently repeated, ice locally or poultices, whichever is most agreeable to the patient, counterirritation by turpentine stupes or iodine, morphine to relieve the pain, and circulatory stimulants as need arises.

Bronchitis in Children.—Solis-Cohen uses counterirritation to the chest, inhalation of creosote or formalin, calomel, gr. ¼ when needed, and:

℞ Tinct. Aconiti..... ♏ i
Tinct. Opii Camph..... ♏ ij
Vin. Ipecac ..... ♏ v.

Sig. Every two hours. He says that alcohol or quinine do little, if any, good.

Facial Neuralgia.

℞ Tincture of Aconite Root..... ʒiv
Chloroform ..... ʒiv
Alcohol ..... ʒiv
Oil Peppermint..... ʒi.

M. Sig. Apply with a camel's hair brush.

Ipecac in Atonic Dyspepsia.

℞ Tr. Physostigma ..... 6 parts
Tr. Ipecac ..... 1 part
Tr. Star Anise..... parts q. s.

M. Sig. Six drops in a glass of vichy, after each meal.

℞ Tincture of Ipecac.....
Tincture of Calumba.....
Tincture of Gentian ..... aa.

M. S. From fifteen to thirty drops after each meal, in two portions from half an hour to an hour apart, in a little water.—*Mathieu, Lyon Médical.*

Facial Erysipelas.

℞ Carbolic Acid ..... ʒi
Tinct. Iodine ..... ʒi
Alcohol ..... ʒi
Oil Turpentine ..... ʒij
Glycerin ..... ʒiij.

The lesions to be painted with this every two hours, and covered with gauze.—*La Presse Médicale.*

Copper Phosphate in Tuberculosis and Chlorosis.

℞ Neutral Acetate of Copper.... gr. 1.6
Crystallized Sodium Phosphate, gr. 5.6
Licorice and glycerin, q. s. to make one pill.

Two pills to be taken daily.—*Le Progrès Médical.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 22, 1900.

THE ACUTE INFECTIOUS ORGANISMS.

RECENT investigations are tending to alter our ideas relative to the modes of infection in those diseases which are caused by micro-organisms. It was assumed that any given micro-organism produced a disease which ran a typical course and induced similar pathologic changes in different individuals. The important fact that it is not necessary to account for great variations in a symptom-complex by assuming a mixed infection, but that one and the same organism is capable of assuming a double rôle, at least, is being more clearly recognized.

We present a study in this week's MEDICAL NEWS by Dr. Wasdin in which he shows that many organisms, especially those of yellow fever and of the plague, exhibit this dual action.

The study of yellow fever in man and in animals naturally produced led him to investigate the prevalence of several types of cases encountered in this as well as in many of these infections. He concludes from the facts gained from these experiences that the variations in the types of disease processes depend on the development of two inherent qualities in these organisms, those of toxicity and septicity. The former quality when developed produces the toxemias, the latter the septicemias. Intermediate between a perfect toxemia and a perfect septicemia, the latter unknown in these acute infections in man, there may exist a mixture of these conditions, sepsis always being secondary to a more or less accentuated primary intoxication.

Applying the facts derived from the study of this one acute epidemic infection, yellow fever, to the other infections, in the light of recent experimental knowledge, he arrives at the formulation of a law which governs the production of these different types, heretofore known, in yellow fever, as the *ephemeral, grave* and *siderante* types of the disease, and shows that these three types must exist, more or less clearly marked, in *all* the infectious diseases, being especially marked in those of epidemic character.

The expression of the belief that all the acute infections may be contracted from the respiration of the specific organisms is not startling, since this has been recognized as possible in the case of all of them with the exception of typhoid fever, plague and tetanus.

The recognition of the facts affirmed by the writer, that all cases of plague, not due to artificial infection by means of wounds of the integument, are primarily respiratory, and that the three types of plague are to be expected, the ephemeral, possibly ambulating cases, the grave or classic bubonic type, and the siderante type, must materially assist efforts made to limit any outbreak of this dread disease, a possibility not so remote in view of its rapid extension to this continent. The diagnostic recognition of the ephemeral and foudroyante cases of plague will present greater difficulties than that of the classic type, with buboes, still too much stress cannot be laid upon the importance of such recognition, for these cases are relatively of greater sanitary importance than those of the well-marked type. Regulations directed to the detection of plague at quarantine should include careful inquiry concerning all diseases of the respiratory tract and especially of any cases of "sudden death" or death after short illness. Ill-defined pneumonia and bronchitis should invite particular attention. The presence of glandular enlargements, buboes of considerable size, may be encountered, the patients offering no other evidence of disease. Careful bacteriological examination of the sputum in these suspected cases should be made, both by the ordinary methods and by mixing the secretion, preferably carefully dried and powdered, with the food or in the bedding of white mice, which are so susceptible to the acute infections. Of all the organisms closely resem-

bling bacillus pestis, there is not one that will naturally infect these animals. Such natural infection will corroborate results obtained by the practice of the ordinary and routine methods of artificial infection of animals, and will remove much of the skepticism, both lay and professional, as to the presence of the disease.

The expression advanced in this article, that typhoid fever belongs in this group of respiratory diseases and that the three cardinal types must be encountered also, is one of importance. The experimental work of Sanarelli was productive of the conclusion by that writer that the intestinal canal was not solely involved in typhoid fever, although this infection has been produced by mixing the bacillus typhosus in the food of rodents. The writer holds that the rapidly increasing literature of such cases must accentuate the statement that most cases of typhoid fever are primarily respiratory in origin, and he attracts attention to the futility of endeavoring in any community to entirely suppress the disease by the provision of filtered drinking-water only, while the supply for civic and household purposes remains contaminated, the use of which means the dissemination of the infective germ by dust-carriage in the streets and within the house. All water-supplies should be filtered, but more attention should be paid to that destined to be sprinkled on streets and lawns and for laundry and other household uses.

The detection of ephemeral cases of typhoid must also be extremely difficult and is of secondary importance only to the detection of such cases of plague. The prohibition of the unclean habit of expectorating on the streets and in public places, should be enforced in the interest of the public against plague and typhoid fever, as well as against pneumonia and tuberculosis. All of these acute infections may be respiratory diseases, therefore we should protect the vulnerable tissues of the lungs against the entrance of their specific organisms.

HOSPITALS AND LAY MANAGERS.

The troubles in the Board of Governors of the Hospital for the Paralyzed and Epileptic in England seem hardly worthy of so dignified a group of men. Their excuses and petty reasons for not allowing representatives of the medical staff confer with them on the subject of hospital management reminds us strongly of the attitude of a worthy board of fashionable women who "managed" an annual garden-party and incidentally a small hospital in a philanthropic city hard by. These good women would permit no medical representative upon their board and no wife or female relative of any of the staff among their number, "for fear of unpleasantness which might arise from possible criticism of the staff;" and yet the urgent petitions of the staff for the purchase of an efficient disinfectant were completely ignored at successive meetings, owing to the pressure of business anent the garden-party. When the board did occasionally give time to the discussion of the medical side of their charity it was to deplore, in the same tones with which they discussed their servants, the tendency of the staff to retire every twelve months.

That a medical staff composed of some of the ablest physicians in England should be subjected to like illogical exclusion from the hospital management and that the dignified governors of the hospital should place themselves in the position parodied by the feminine board referred to seems inexplicable to our minds.

The very existence of a hospital implies the willingness of good-hearted people to give their money and able physicians to give their services. The more eminent the physician the less time he has and no one would dream of asking him to render other than medical services to the hospital. The lay managers or directors of the board assume, for purely philanthropic purposes, the burden of the details of the management; but it is taken for granted that both sets of individuals are working for the same altruistic end, the good of the sick man. No one will for a moment deny that the physicians are the power by which this end is attained and that the lay managers are their assistants and cooperators. In other words, the principles of sanitation, the régime of diet, the methods of treatment, the manner of nursing must of necessity emanate from the physicians who by virtue of their busy lives must leave the details to be worked out under the direction of laymen.

This naturally puts the directors in positions of authority on all questions of routine management, and might with narrow-minded men lead to a usurpation of power that would seriously militate against the good of the hospital.

Most of the larger and best managed hospitals in America vest executive power in the medical staff, either in the form of a medical committee, or a representative, or the appointment of a medical man as chief executive officer of the hospital.

This is no concession to their claims, but is merely to save the other physicians time and energy.

That eminent physicians who are carrying on advanced scientific treatment should be obliged to beg for a voice in the management of the work of which they are the very impulse seems laughable. Whether or not the diet of the hospital in question was sufficient or the management satisfactory, the principle remains that the medical man must be free to advise and to cooperate with the directors of the hospital, and they in turn must be sufficiently in touch with the medical men who are serving the cause to be able to choose those with whom they can openly discuss all medical affairs of the hospital without hurting their feelings.

BACILLUS TYPHOSUS AND SEWAGE-DISPOSAL.

For several years past the modern system of sewage-disposal has been by septic tanks and bacterial filters made of coke or gravel. It was at first held that this modern improvement over chemical or land treatment of sewage effectually did away with all or most of the pathogenic bacteria. Sewage products treated by this plan were allowed to flow from the bacterial beds into rivers, with the idea that all infection was effectually disposed of. The persistence of epidemics of dysentery and typhoid led many to doubt whether this plan of sewage-disposal was as effective as was at first thought. A series of experiments was carried out in 1894 by Andrewes and Laws on the vitality of the bacillus typhosus in crude sewage before undergoing treatment for purification. Crude sewage was found to be not only an unfavorable medium for the typhoid bacillus, but certain sewage bacteria were directly prejudical to the growth of the typhoid germ. Nevertheless this was not as reassuring as it might have been, for it was discovered that, while the raw sewage was not a good growing medium, the typhoid germ maintained life for days and even weeks, and thus gave the bacilli excellent opportunity to pass beyond the sewage system, and develop in a more encouraging medium.

A little later in the same year Klein proved that the typhoid bacillus not only lived for weeks, but that the nitrate sewage, the kind most favorable for bacterial filter disposal, permits the greatest longevity to typhoid bacteria. In this light the coke-beds are storehouses, and we must infer that no bacterial sewage-disposal holds the sewage long enough to terminate the life of the bacillus typhoid coming to it in crude sewage, hence the explanation of the contagioned water supplies near or below the river discharge from large towns having a typhoid epidemic. To-day many English authorities go as far as to say that crude sewage is probably but little worse than river discharge from sewage-beds.

In a recent discussion of the whole matter in question, at the annual meeting of the British Medical Association (*Brit. Med. Jour.*, August 18, 1900), Dr. Houston detailed a series of observations that he carried out at the instigation of the London Common Council, on coke-bed filters at Crossness. On account of the extreme difficulty and impractibility of isolating the bacillus typhosus, he took the more common and more abundant bacillus coli and bacillus enteritidis sporogenes, one aerobic and the other anaerobic. He found that the so-called biological processes at work in the coke-bed had no appreciable effect on the reduction of the number of these bacilli, compared with the quantity found in crude sewage.

We therefore infer that the bacillus typhosus which is more resistant to the bacterial filter escapes destruction, thus we have striking proof that from an epidemiological point of view the present sewage-disposal by septic tank and bacterial beds is fully as dangerous as the old cesspool, the overflow and leakage of which have been responsible in the past for such frightful mortality. In closing the discussion, Dr. Houston held out some hope that the danger of contaminating river water by the effluent from bacteria beds would be considerably lessened if the discharge was passed over land or sand-beds similar to that done for the purification of drinking water. Unless sewage can be disposed of in the future in such a manner as to become inocuous, we must continue to expect epidemics of typhoid and dysentery wherever the possibility of contaminating the water-supply may exist. The present septic tanks and bacterial filtration-sewage system must be set aside or modified, so that it will cease being a menace to public health by arousing false hopes of security.

The Medical Center of America.—Dr. I. N. Love, editor of the *Medical Mirror*, removed to New York, as he terms it, "the medical center of America," September 15, 1900. The *Mirror* is to be published in St. Louis as formerly.

ECHOES AND NEWS.

NEW YORK.

Obituary.—Dr. Frank C. Merriam of 136 West Eleventh Street died September 16th, at Waterford, Conn. He was forty-six years old and a graduate of the University Medical College, class of 1880. He leaves a wife and three small children.

Telephone Burglar.—This species of malefactor is abroad. Under the guise of a kit of tools and the tale of repairs to the wire, he obtains entrance to houses and then leisurely ransacks them. Make him show his badge and if not then certain get his name, call up central and see if his name and number are authentic.

Charitable Bequests.—By the will of George D. Sweetser the following institutions are benefited: Home for Incurables, Woman's Hospital, House of Rest for Consumptives in Tremont, New York Infant Asylum, New York Society for the Relief of the Ruptured and Crippled, and the Skin and Cancer Hospital.

Pink Eye and the Baths.—Dr. Cary of the New York Eye and Ear Infirmary has decided that the public baths along the rivers' front are responsible for an epidemic of pink eye similar to the one which broke out in Brooklyn two weeks ago from the same cause. One hundred and ninety-six cases of the disorder were treated at the infirmary in one day.

Building at Columbia.—After several years of effort, the alumni of the several schools of Columbia University have succeeded in raising the necessary $125,000 for the erection of the second story of the University Hall. Work was begun last week and the building operations will be hastened, as it is the desire of the graduate associations to hold their annual reunion exercises next June in the memorial chamber of the new story.

Free Milk.—The free distribution of pasteurized milk, which has been carried on since July 17th by the Bureau of Charities in cooperation with the health authorities of the Borough of Brooklyn, was discontinued Monday. For nine weeks, during which time the plant has been in operation under the arch of the East River bridge on Main Street, there has been an average daily distribution of between 1600 and 1700 six-ounce bottles of pasteurized milk, prepared especially for children. Notwithstanding the unusually hot weather, the statistics in the office of the Board of Health show that the rate of infant-mortality has been lower than for the same period during the five years preceding, and some of this result is attributed to the distribution of the pasteurized milk. According to the official figures, the deaths among children under five years during three summer months of several years have been:

	From diarrheal diseases.	From all causes.
1895 (no milk)	1212	3206
1896 (no milk)	1197	3307
1897	990	2930
1898 (no milk)	1122	3092
1899	993	2909
1900	931	2858

If the milk could have been more widely distributed, the good results would doubtless have been more marked. Some of the thickly populated portions of the city were not reached at all. It is to be hoped that another summer the work may be conducted on a larger scale. All who are willing to help in defraying the unpaid expenses of the work for the past summer are requested to send their contributions to the central office of the bureau, No. 69 Schermerhorn Street.

Famous Patient Dies in Bellevue.—"Tommie" died in Bellevue Hospital September 16th of Bright's disease. He was well known at Bellevue for having undergone an operation by which his finger was grafted to his face for a nose, that organ having been eaten away by a tuberculous ulcer. The operation was performed by Drs. Lewis A. Sayre and Thomas Sabine of the College of Physicians and Surgeons, after others had agreed that the man's case was hopeless.

PHILADELPHIA.

Death from Broken Back.—Edward Knouff, a fireman, died recently at the German Hospital from injuries received in April, 1897. His back was broken by the fall of a stone. The case attracted much attention at the time.

Death from Circumcision.—A fifteen-day-old infant died from hemorrhage following circumcision by a rabbi last week. A physician was called after unsuccessful efforts to check the hemorrhage had been made for two hours. The child died five hours after the physician was called to see the case.

Pennsylvania Hospital.—A new entrance building is being constructed at a cost of $60,000. The kitchen in the basement is to be equipped with an electric air-blower and fan to remove the odor of the cooking.

Dr. Linnaeus A. Smith.—The death of this physician occurred September 12th. He was well known from his treatment of skin diseases by homeopathic methods. Some years ago he removed to Jamaica, after evolving a system of treatment to arrest the progress of leprosy. Jaundice contracted there led to his death.

Formaldehyde in Milk.—A milk dealer in Upper Darby has been held for a hearing on the charge of selling milk containing formaldehyde. The use of the drug is said to be quite prevalent among dealers in order to save ice.

Physician Robbed.—Dr. W. H. Klopp found upon returning to the city from his vacation that thieves had taken furniture, clothing, etc., to the value of $700 from his house during his absence.

Beulah Orphanage Case.—The Grand Jury has indicted Sheets and Sollenberger, religious enthusiasts, for the murder of a seven-months-old infant last July. The men conducted the "Beulah Orphanage" on faith-cure principles. A physician was called to the case too late, but the keepers' "consciences pricked them for faltering in faith" and they decided never to call another physician.

German Hospital.—The ambulance of this hospital was recently hindered by a teamster refusing to give the right of way. At a hearing the teamster was fined $5.00. Upon his statement that other teams prevented his turning out the fine was remitted and he was discharged after a severe reprimand by the magistrate.

Free Hospital for Poor Consumptives.—This organization is still endeavoring to secure a building of its own. It now has under its care 31 patients distributed among four hospitals in the city and one in the Adirondacks. During the first six months of this year 116 patients were cared for at an expense of $4600. The general hospitals are practically closing their doors to consumptives, even those for whom they are paid not being desired.

Sanitarium Season Ended.—The Children's Sanitarium at Red Bank has closed the most successful season in its history. The admissions for the 73 days were 180,670. The institution comprises a hospital, soup-house, infants' bath-house, swimming pools, etc.

The Galveston Relief Fund.—This fund now amounts to over $45,000 for the Permanent Relief Committee in addition to other funds which have been started by individuals and firms. Benefits are to be given by several theaters and two train-loads of supplies have been sent. Dr. J. V. Shoemaker in behalf of the Philadelphia and Medico-Chirurgical Hospitals offered the services of 25 nurses to be sent at once if they were needed.

Greek Commander Offended.—The captain of the Greek warship "Miaulis," now in port here, was greatly incensed by the quarantine physician as the vessel came up the Delaware. He states that contrary to the laws of peaceful nations the physician would not accept the count of the crew as given him, but insisted on lining them up and counting them himself. It is stated that the authority in question is a new incumbent.

CHICAGO.

Post-Graduate Medical School.—The capital stock of this institution has been increased from $20,000 to $40,000.

Mount Sinai Hospital.—A hospital bearing this name has been incorporated by Drs. Rudolph Menn, George M. Silverberg, and Adolphus E. Berting.

Boulevard Sanitarium.—An institution of this name has been incorporated with a capital stock of $2500 by Drs. Harry Jay and Wellington P. Stewart, and W. Clark Allen.

Dr. Ochsner.—Dr. A. J. Ochsner has been appointed Professor of Clinical Surgery in the Medical Department of the University of Illinois (Chicago College of Physicians and Surgeons).

Health Department of Chicago.—This department has been awarded one of the grand prizes at the Paris Exposition for its exhibit of blanks, charts and other forms in use at the office of the department.

Control of Drainage Canal.—Controlling works at the junction of the river and the sanitary canal are favored by the Health Department, which deems such works necessary. At the present time it requires from eight to twelve hours to shut the gates at Lockport and stop the current, and during this time the garbage and sewage are prevented from taking their natural course through the canal, and the health of the city is thereby endangered.

Tribute to Dr. Schmidt.—The Board of Trustees of Michael Reese Hospital has adopted resolutions upon the death of Dr. Ernst Schmidt, who served that institution with great efficiency for the period of twenty years.

Mechanism of Dislocations of Hip.—Dr. Oscar H. Allis of Philadelphia, as the invited guest of the Chicago Surgical Society, will give a demonstration (upon the cadaver) of the mechanism of dislocations of the hip and their reduction, by manual effort and without previous tenotomy of the capsule, in the amphitheater of Rush Medical College at 8 P. M., October 5th. The annual dinner, at which Dr. Allis will be the honored guest of the Society, will precede the demonstration.

Cremation.—Popular prejudice against cremation is gradually decreasing in Chicago. Evidence of this is not lacking. The people are becoming more liberal on the subject and are getting over the idea of horror that used generally to attach to incineration. Less than fifteen years ago there were three crematories in the United States and they were scarcely used. At present there are nearly fifty scattered throughout the country, and the number is increasing every year. They are in the larger centers of population, where the demand is greater and the facilities for successful operation are better. The crematory at one of the cemeteries in this city exemplifies in a great measure how fast the prejudice is falling away. Since the erection of the plant in December, 1893, the records show that 616 bodies have been incinerated.

Chicago in Professional Education.—Statistics show that Chicago is fast becoming the professional school center of America. There are twenty medical colleges alone. There is no reason why Chicago should not lead in this respect. A medical college needs a large city to supply patients for the training of students, and the hospitals furnish such an opportunity and make possible the study of a greater variety of diseases. This is the reason why London, Berlin, Paris, and Vienna are great medical centers. The large cities also draw to them the greatest physicians, as it is there that the practitioners can earn the largest fees, and these men are glad to devote some of their time to giving lectures to students. In the same way the methods of legal procedure can best be learned in a large city. With such metropolitan advantages, together with the fact that Chicago is so near the center of population of the country, there is every reason to expect that its usefulness in this respect will increase constantly, and the city will become the American center for legal and medical instruction.

Papyrus Ebers.—For twenty-three hundred years Hippocrates of Kos has been known to the world as the "Father of Medicine." This distinction, however, has been wrested from the ancient Greek by the discovery and translation of an early Egyptian papyrus treating of the subject of medicine, with date so remote as almost to place Hippocrates within the ranks of modern physicians. English medical literature is about to be enriched by the translation of this papyrus, generally admitted by Egyptologists to be the oldest book devoted to the science of medicine extant. The work is known to scientists as the Papyrus Ebers and is supposed to have been written during the reign of Bicheres, a king of the fourth dynasty, 4688 to 4666 B. C. Thus the original document is nearly 7000 years old and it contains the written genesis of the art of healing. Although brought to light in 1873, no complete translation of the papyrus Ebers has been made. The document is carefully preserved in the library of the University of Leipsic, and it remained for a Chicago man to make the first English and the only complete translation. The work was undertaken about a year ago by Dr. Carl H. von Klein of Chicago, a well-known student of the Oriental languages and the author of a number of medical works, among them a book on the "Medicine of the Talmud." His English translation of the papyrus Ebers, a volume of several hundred pages, will soon be ready for the press.

GENERAL.

The Plague at Glasgow.—There has been a distinct increase in the number of plague cases at Glasgow. Five were discovered in one day. The total now is about 25.

Women Doctors in Austria.—An imperial decree issued September 15th admits women to practice as physicians and chemists on the same conditions as men.

Obituary.—Dr. Dennis Dowling Mulcahey died September 12th at his home in Newark after an illness of a few days. He was born in Tipperary, Ireland, in 1848, and studied medicine before coming to this country.

Galveston Reports.—The State Health Officer, Dr. Blunt, believes that there is now no danger of an epidemic. The city Board of Health held a meeting this week and adopted a resolution voicing the same views. Emergency hospitals have been established in every ward for the treatment of the sick and wounded. The Ursulin Convent has been converted into a great general hospital for the reception and care of patients who are seriously ill, with a full corps of physicians and trained nurses. All public and private hospitals are filled to their capacity with sufferers. Medical supplies are still much needed.

Harvard Items.—Professor William James is again at the Nauheim baths in the hope of further regaining his health. It is not decided whether he will pass the coming winter abroad or in Cambridge.—Professor W. T. Porter, of the Department of Physiology, will be abroad during the next school year. The success of the new practical course in physiology which he has organized has been pronounced.

German Naturalists and Physicians.—The seventy-second annual meeting of the Congress of German Naturalists and Medical Men took place this week at Aix-la-Chapelle, September 16th-22d. Among the papers read were "Development of Scientific Medicine," Prof. J. H. Van t'Hoff of Berlin; "The Neuron in Anatomy and Physiology," Prof. Verworn of Jena; "The Neuron Doctrine from the Pathologic and Clinical Standpoint," Dr. Nissl of Heidelberg; "On the Development of Biology," Prof. Hertwig of Berlin; "On the Development of Pathology," Prof. Chiari of Prague.

Tri-State Medical Society of Alabama, Georgia and Tennessee.—The twelfth annual meeting of the Tri-State Medical Society will be held in Chattanooga Thursday, Friday and Saturday, October 11, 12 and 13, 1900, during the reunion of the Army of the Cumberland and the Spanish-American War Veterans. A fare of one fare for the round trip will doubtless be given the latter from all parts of the country. The South Eastern Passenger Association has already given this rate and the other associations will take up the matter shortly. A large attendance is expected and an unusually good program is in prospect. All desiring to present papers should send title to the secretary, Dr. Frank Trester Smith, Chattanooga.

Medical College Crippled.—The storm caused a loss of probably $70,000 to the buildings of the

State University in Galveston. The medical branch of the institute was situated there. The Brackenridge Building which was recently erected at a cost of $45,000, was wrecked, and the other buildings were greatly damaged, all of them being unroofed. The session was to have opened on September 26th. A meeting of the regents was held at Galveston on Monday and steps taken to accommodate the students in some manner. If it is found that they cannot be accommodated at Galveston they will probably get room in the main buildings of the university at Austin temporarily.

Obituary.—Dr. Hunter McGuire, who was chief surgeon of Stonewall Jackson's army during the war, and one of the most eminent surgeons in the South, died at Richmond, Va., September 19, 1900. Dr. McGuire was the President of the American Society of Surgeons. At the outbreak of the war he was attending the University of Medicine of Philadelphia. He left at once and came to Richmond and enlisted as a private in the Confederate army. Before long he was promoted to be Medical Director of the Second Army Corps. In 1865 he was elected professor of the Virginia Medical College, holding the chair until 1880. He organized St. Luke's Home for the Sick, in Richmond. In the International Medical College of 1876 he was elected Vice-President. The University of North Carolina conferred upon him the degree of LL.D. He was the author of several medical works and of an account of the wounding and death of Stonewall Jackson.

Pennsylvania State Medical Society.—The fiftieth annual meeting of the State Medical Society met this week at Wilkes-Barre, September 18, 19, 20th. The attendance was large, over 300 members registering by Thursday morning. The social features were very pleasant, the Luzerne County Medical Society proving itself a most thoughtful host. The scientific program was of high order. We will present the proceedings in full in next week's issue of the Medical News. The following officers were elected for the ensuing year: President, Dr. Thos. D. Davis of Pittsburg; 1st Vice-President, Dr. W. B. Ulrich of Chester; 2d Vice-President, Dr. L. H. Taylor of Wilkes-Barre; 3d Vice-President, Dr. A. A. Eshner of Philadelphia; 4th Vice-President, Dr. M. L. Kirk; Secretary, Dr. C. L. Stevens of Athens; Assistant Secretary, Dr. W. L. Pyle of Philadelphia; Treasurer, Dr. G. B. Dunmire of Philadelphia. The place of meeting will be Philadelphia; the time, the third Tuesday in September, 1901.

Vaccination and Malpractice.—A physician employed by the Board of Health of New Bedford, Mass., as a public vaccinator has recently been subjected to an annoying criminal prosecution for vaccinating a child five months old. The charge was assault and battery. It appeared that the defendant, while engaged in the work of vaccinating in a tenement district, visited the home of a Mrs. B., and ascertained that her six-year-old boy had not been vaccinated. He thereupon vaccinated the lad without any objection on the part of the mother, who, however, remarked to him at the time, "You won't have to vaccinate my baby, will you?" The doctor answered that he thought he would, and in response to further objections by the mother told her that she would have to settle them with the Board of Health. He then proceeded to vaccinate the baby. It was proved without contradiction that the mother, notwithstanding her remonstrances, bared the infant's arm for the operation; and the court acquitted the defendant on this ground, holding that it was convincing evidence that the complainant, although undoubtedly reluctant, had finally consented that the child should be vaccinated.

Lodge Doctor.—A medical controversy, growing out of the willingness of certain doctors to treat the members of fraternal and benevolent societies at reduced rates, is about to be carried into the courts of Massachusetts at Springfield. The Hampden County Medical Association has expressed its disapproval of this practice, insisting that no special arrangements for charging less than the ordinary fees should be made with these organizations, but the societies seem to have found no difficulty in securing the services of other physicians who agreed to treat their members for a stipulated sum per annum. Thus far there was no room for litigation. It appears, however, that a patient who was sent by one of these so-called contract physicians to the Mercy Hospital in Springfield was refused admission to that institution unless the doctor in attendance withdrew from the case, which he finally consented to do for the sake of the patient, who required treatment which could be afforded only at a hospital. A suit will now be brought to ascertain whether the hospital staff could lawfully take this action under its charter, which provides that all patients shall be treated there who are brought to the institution by reputable physicians.

No Hydrophobia in England.—The State Department has received from Lord Pauncefote, the British Ambassador, a memorandum as to the importation of dogs into Great Britain. By enforcing the strictest regulation in regard to muzzling and the importation of dogs the disease of rabies in dogs and hydrophobia in man has been practically stamped out in England. Under the present ruling of the Board of Agriculture licenses must be obtained for the landing of dogs in Great Britain and a penalty of £20 and the possible seizure of the dog is enforced when a license is not obtained. Masters of vessels are liable to prosecution if dogs are landed illegally, and cannot accept dogs for shipment to Great Britain unless the license is shown at the port of embarkation. Imported dogs are isolated

for from four to six months and are moved about only upon license from the board. When taken out for exercise they must be properly muzzled and in charge of competent persons. The memorandum says: "The experience of the board has clearly shown that the frequent movement of pet dogs to and from the Continent involves this country in serious danger, inasmuch as a pet dog may become infected with rabies without the knowledge and despite the utmost care on the part of its owner. It is therefore a matter of great importance to owners of dogs in Great Britain that dogs from abroad should only be admitted in instances where it has been satisfactorily established that some useful purpose will be served by their admission, or where a pet dog would otherwise be separated from its owner for a prolonged period. Pet dogs should not be taken abroad and thus exposed to the risk of infection, excepting cases of real necessity."

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, September 8, 1900.

THE SOUTH AFRICAN HOSPITAL SCANDAL—ACCUSATION BY MRS. RICHARD CHAMBERLAIN—DISPATCH OF A COMMISSION TO SOUTH AFRICA TO INVESTIGATE THE NATURE AND PREVENTION OF THE EPIDEMIC OF TYPHOID FEVER AND DYSENTERY IN THE ARMY—RESULTS OF THE VACCINATION ACT ABOLISHING COMPULSION—NO DIMINUTION IN VACCINATIONS—IRISH POPULATION STATISTICS.

Public attention is still riveted on what the lay press call the "War Hospital Scandal." The latest contributions of importance are the statements of Mrs. Richard Chamberlain, sister-in-law of the Colonial Secretary, who went out early in the campaign and nursed in the hospitals around Cape Town. According to her, "Every word that Mr. Burdett-Coutts said, and much more, is true." The base hospitals at Cape Town, where everything necessary was at hand, and which ought to have been in as good condition as the London hospitals, were worse than the field hospitals. No attempt was made to clean them before they were used, with the result that the patients had to be covered with insect-powder to keep off the vermin. Although the scandalous state of affairs was brought under the notice of the military authorities, they did nothing. The nursing staff was inadequate—one sister to every 175 men for night and day. Yet there were any amount of sisters in Cape Town who had come from Johannesburg and would have been glad to have accepted situations.

The Government has decided to dispatch immediately a commission of experts to South Africa to investigate the nature, cause and prevention of dysentery and typhoid fever which have been so fatal to the soldiers. As usual they are waking up late in the day to a sense of their responsibilities and are learning a little in the dear school of experience. In the House of Commons, when the war was beginning, Sir Walter Foster proposed the appointment of a sanitary commission to assist the military authorities in maintaining the health of the troops, but the Government in its superior wisdom rejected his suggestion. The Commission consists of Dr. W. J. Simpson, Professor of Hygiene in King's College, London; Professor Notter of Netley, and Mayor Bruce. Professor Simpson's career eminently fits him for his appointment. In 1881 he was made medical officer of health for the town of Aberdeen, which appointment he held until 1886, acting also as lecturer on hygiene at the university. He was then appointed medical officer of health for Calcutta. He is the author of several valuable papers on public health matters and visited Egypt during an outbreak of cholera. He prepared a report on his visit for the English Local Government Board. His career in India was attended by considerable success and he is an authority on anticholera inoculation.

The death of Sir William Stokes at Pietermaritzburgh removes from the Dublin profession its most prominent and distinguished surgeon. He was a member of a family famous for generations in medicine and well known also in other branches of science. His father was the celebrated physician, William Stokes, who did such admirable work on the subject of diseases of the chest. His grandfather was Dr. Whitely Stokes, who also filled a prominent position both in the profession and in public life. He was a member of the Society of United Irishmen, but left that body when its method became revolutionary. Wolfe Tone wrote of him he was "the very best man I have ever known." Sir William Stokes has been professor of surgery at the Royal College of Surgeons for nearly thirty years. His method of amputating at the knee-joint—a modification of Gritti's—is known as Stokes' operation. He made many other valuable contributions to surgery and also possessed considerable literary power. Referring to his presidential address on surgery at the meeting of the British Medical Association in 1882, the *Boston Medical and Surgical Journal* said it produced "an unmixed expression of delight and proved him, as a medical orator, scarcely, if at all, second to Sir James Paget." In a city of eloquence he was famous as an after-dinner speaker.

The new Vaccination Act which abolished compulsion has not proved injurious, as was expected. Exemption is granted in the case of the children of parents who declare before a magistrate that they have a conscientious objection to

vaccination. In 1898 previous to the passing of the Act the number of children vaccinated was 500,314; in 1899, after it was passed, 669,349. This increase cannot be explained by an increase in the number of births which were only 5000 more in one year than another. The proportion of successful vaccinations to births has risen from 54.2 to 72.1 per cent. It seems that the disappearance of what many Englishmen regarded as harsh and oppressive measures of compulsion, repeated fines, etc., has diminished the objection to vaccination.

The report of the Irish Registrar General for 1899 illustrates the old story—continued depopulation by emigration. While the natural increase of population—that is to say, excess of births over deaths—was 24,201, the loss by emigration was 41,232, the decrease in population during the year being thus 17,031. With this report some very instructive demographic facts for each of the years from 1880 to 1899 are issued in the form of a chart. In 1880 the marriages were less than 4 per 1000; they are now 5 per 1000. In 1880 the deaths were almost 20 per 1000; they are now only 17.6. But against these figures must be placed the fact that the birth-rate has decreased in the same period from 24.7 per 1000 to less than 23. In 1889 the non-Roman Catholic marriages were 6.06 per 1000 and in 1898, 6.31; the Roman Catholics were 4.09 and 4.53, respectively. Thus the marriage-rate is 2 per 1000 greater amongst other sects than Roman Catholics. The fall in the birth-rate is most remarkable. It shows that the Irish race, proverbially prolific, is involved in the modern tendency to a diminished birth-rate. The emigrants were mostly in the prime of life and went principally to the United States.

TRANSACTIONS OF FOREIGN SOCIETIES.

French.

HISTOLOGY OF PLEURITIC EXUDATES—SYNOVITIS OF THE KNEE—DIFFUSE ANEURISM OF THE EXTERNAL ILIAC—ENUCLEATION OF FIBROMATA UTERI—PERMEABILITY OF THE PLEURA TO SODIUM SALICYLATE—HEMORRHAGIC INTESTINAL NECROSIS—PRIMARY PNEUMOCOCCUS PERITONITIS—THE VISCERA IN THEIR RELATION TO POISONS—RECOVERY FROM APHASIA.

WIDAL and RAVAUD at the Société de Biologie, June 30, 1900, said that only the exudates of cancerous pleurisy had often been subjected to careful histological examination in the expectation of finding cancer-cells, while the products of ordinary serofibrinous cases had been neglected. Their conclusions are drawn from fifty-six cases, to the effect that examination of the scattered cells in the fluid is capable of giving valuable pathological and clinical data. By exploratory puncture with a sterile needle several cubic centimeters are withdrawn, defibrinated before or after coagulation, centrifuged, stained after having spread the emulsion upon slides with a platinum loop and not as with blood by means of a glass "spreader." The following seem to be the distinguishing features of the various forms of the disease: (1) Idiopathic pleurisy (still sometimes called "cold" and proved by Landouzy to be practically always tuberculous) has almost exclusively small lymphocytes, mingled often with red cells, appearing usually about the ninth day. It would be instructive to observe the exudate earlier. (2) Pleurisy in the presence of tuberculous caseation and excavation of the lungs presents very few elements even after centrifuging, a few red globules and lymphocytes; more numerous polynuclear cells, old, deformed, degenerated, fragmented nuclei filled with neutrophile granules; also a few altered degenerated mononuclear leucocytes, and some amorphous masses without nuclei, which are commonplaces in all exudates. (3) In the pleurites of cardiac, renal, cancerous or pressure origin we find large exfoliated endothelial cells, red blood-cells, and lymphocytes surrounding them and enabling a diagnosis at once. They may occur single, double or in large sheets, a veritable desquamation. (4) Streptococci pleurisy shows only neutrophile polynuclear cells with deformed nuclei. (5) Pneumococci pleurisy has red cells, lymphocytes, many lymphocytes, many mononuclear cells, chiefly of endothelial origin, some inclosing in the cell-body polynuclear cells. (6) Typhoid pleurisy is always bloody and may have large mononuclear leucocytes. (7) Eosinophile cells were found in a case of tuberculous, of typhoid and of parasitic pleurisy. Thus it may be seen that practical significance attaches to the examination of the exudate in inflammation of these serous membranes.

POTHERAT, at the Société de Chirurgie, July 18, 1900, outlined a case of thickening of the synovial membrane of the knee which simulated movable foreign body. All the typical symptoms of the latter were present and the supposed body was so much in evidence and function, so much limited, that arthrotomy was done. The free exposure of the joint-cavity gave to view a large thickening of the synovia in the deep folds beneath the triceps femoris and two others opposite, beneath the quadriceps femoris. All were easily ablated. Full recovery of function followed. Histologically the growths were tuberculous.

ROUTIER reported a case of diffuse aneurism of the left external iliac. The patient was sixty-four years old, in perfect health up to March, 1900, except for moderate early signs of bladder trouble necessitating the occasional use of the catheter. That month he was attacked by slight pain about the left sacro-iliac joint and a little later by sudden pain in the left groin while on a voyage. A median laparotomy was done, and the tumor, which had given all the signs of aneurism, was found to be such. The external iliac

was ligated as close to its source as safe and the femoral artery high up. Several clots were turned out and hemorrhage controlled by clamps left *in situ*. Recovery was well under way when on the tenth day after the operation trismus followed by death set in, without any local or systemic prodromata. Death was due to tetanus, although the speaker had not seen any cases of it in his hospital or private practice.

Tuffier said that enucleation of fibromata is a just, conservative procedure, and preferable to hysterectomy for the same trouble. He had collected reports of 560 cases, going to show that the operation had passed the experimental stage. His own experience had been fifteen cases, with one death from septic peritonitis. The abdominal operation in this class of work he considers the best and the technic, although more laborious and tedious than simple removal of the whole organ, is such as to make resort to it usually advisable.

Widal, at the Société Médicale des Hôpitaux, July 6, 1900, said that with Ravaud during studies of the histology of the serofibrinous exudates in pleurisy, he was led to experiment as to the permeability of the pleura to sodium salicylate, as was undertaken by Raymond, Tourlet and Castaigne. The author and Ravaud used the drug in doses of 0.30 gram injected first beneath the skin and next into the pleural cavity. It was established that the salicylic acid appears in the urine more rapidly than either methylene blue or iodide of potassium. In the normal individual the elimination occurs completely, on an average in fifteen hours; in some cases in eighteen and even twenty hours. The total excretion oscillates between 0.17 and 0.20 grams. The greatest amount excreted is usually during the first six hours. The two experimental injections (subcutaneous and intrapleural) may be made at very short intervals. The quantity given and voided was weighed very exactly. The permeability of the pleura studied in five case of pneumonic pleurisy the rate and dura- follows: In one case of primary tuberculous pleurisy the permeability was decreased; in one case of pneumonic pleurisy the rate and duration were altered, but not the total elimination; in three cases of mechanical pleuritis, cardiac or renal, there was either no change or a slight augmentation in two and slight decrease in one.

Castaigne in the discussion said that he had investigated the permeability of the pleura to sodium salicylate not only from within outward, but from without inward, by means of subcutaneous injections. Of twelve cases of pleuritis subjected to this procedure, in seven salicylic acid was recovered from the exudate and in five no traces whatever of it were found. Cryoscopic examination of the pleuritic fluid and of the blood serum in these cases showed that the freezing-point was alike in each when the permeability (from without inward) was lost, but slightly different when it was preserved. In comparing these results with clinical facts, the conclusions drawn are that when the permeability is preserved the pleurisy is in the course of invasion and solution; when it is absent the inflammation is established. The practical application is that before doing thoracentesis one should wait until the moment when the subcutaneous injection of the sodium salicylate no longer affects the pleural cavity contents.

Hirtz, at the meeting of July 13, 1900, reported the autopsy findings of a case of hemorrhagic intestinal necrosis due to venous obliteration. The patient was a female, thirty-one years old, afflicted with abundant ascites accompanied by the appearance of collateral circulation, and three days after admission by the sudden onset of violent vomiting and general abdominal pain, and followed by coma and death about thirty-six hours later. At the post-mortem examination were found an old adhesive obliterating portal phlebitis, discoloration of fifty centimeters of the small intestines due to a reddish bloody fluid exudate into their lumen, thickening of the coats of the mesentery and obliteration of the mesenteric veins. A comparison of these and the clinical facts of this with those of other similar cases published seem to indicate the possibility of diagnosticating this condition during life. Its theoretical clinical picture would be as follows: Pain would be an early and important sign; never absent, more or less severe; awakened and aggravated by palpation, or spontaneous and acute, radiating or situate in the renal lumbar, epigastric, or hypochondriac regions, if in the course of a hepatic disease, overshadowing the symptoms of the same; simulating appendicitis, renal, biliary and intestinal colic, intestinal obstruction, etc., and often diagnosticated solely by exploratory incision. In all cases of primary venous obstruction the patients have died in what may be called the *terminal syndrome*. After several weeks of indefinite abdominal distress there comes a violent sudden onset of intense general, at times tearing pain, vomiting, anxious expression and prostration, resembling somewhat a peritonitis. But the lesions are not those of a peritonitis. In fact, bacteriologically the intestinal contents are crowded with germs, fewer and fewer in the coats as we pass outward, and finally the exudate in the general peritoneal cavity has been found germ-free.

Menetrier reported two cases of primary pneumococcus peritonitis in the adult. This disease occurs oftener in children than in adults. His first case seen eight years ago is of interest only from a bacteriological standpoint. A male, thirty years old, suddenly by night was seized with abdominal pain, dying after eight days' agony. Pure cultures of the pneumococcus were obtained from the fluid exudate of the peritoneum, but no focus of their invasion was obtained. The other patient showed many interesting clinical features. A male, thirty-five years old; same onset; later development of peritonitis, followed by subsidence; then pain and

abscess-formation on the sole of the right foot; serosanguinous evacuation; loss of dorsalis pedis pulse; similar abscess in the left hand; decrease in the left radial pulse; recrudescence of the peritonitis; death. The autopsy revelations were: General peritonitis, infarcts of the spleen and kidneys, obliteration of the left radial and right dorsalis pedis, posterior tibial and popliteal arteries by old and of the Sylvian artery by recent clot; all yielded the pneumococcus; normal heart; the peritonitic exudate contained the same germ, but as the post-mortem examination was performed late the bacillus coli communis and the staphylococcus albus were mixed with it. The patient had had a cough fifteen days before these symptoms began.

M. G. Brouardal, at the meeting of July 20th, explained experiments and their results conducted by Thoinot and himself as to the effect of certain visceral substances upon poisons. The method followed was to triturate a known weight of a given viscus with a definite quantity of the poison and inject the mixture into guinea-pigs. The poisons employed were strychnine sulphate, chlorhydrate of morphine, arsenious acid and sulphate of atropine. The results of the experiments are that the organs may neutralize, enhance or not affect the specific action of the drugs. The kidney and the liver appear to be especially active in neutralizing the toxic effects. Muscle tissue renders inert a rather large dose of strychnine, has little effect on morphine and atropine and augments arsenic. Cardiac substance is neutral as to atropine, but increases the virulence of strychnine, morphine and arsenic in descending scale. Lung tissue has no effect on arsenic and feebly combats all the others. Cerebral matter is neutral as to atropine, strongly antagonizes strychnine and morphine, but augments arsenic greatly. Without drawing definite conclusions from these illustrations, they may profitably be compared with those by Teissier (Lyons) along the same lines with toxins.

Antony reported a case of partial recovery from aphasia of eleven years' standing. The patient, a man, thirty-five years of age, had suddenly been stricken with right hemiplegia. Four days afterward consciousness returned, but he was totally unable to answer questions except in a few meaningless monosyllables no matter what the query might be. There was no word-blindness and no word-deafness. The case appeared to be one of cortica motor aphasia with conservation of sung words due very probably to the destruction of the top of the third left frontal convolution. The state of this man had not changed at all till June last, when by some unexplained way he regained certain words.

Water Famine in the Bronx.—The recent dry weather has brought about a dearth of water for the Bronx region. It is feared that typhoid may break out as the water is of the poorest quality. The Commissioner is seeking some relief.

SOCIETY PROCEEDINGS.

CANADIAN MEDICAL ASSOCIATION.

Thirty-Third Annual Meeting, Held at Ottawa, September 12-14, 1900.

The thirty-third annual meeting of this Association was held in the Academic Hall of the University of Ottawa, Ottawa, Canada, under the presidency of Dr. R. H. Powell.

Eliminative and Aseptic Treatment of Typhoid Fever.—Dr. W. B. Thistle of Toronto University in contributing this paper stated that it is now seven years since he introduced this plan of treatment of typhoid fever to the profession. Dr. Thistle claimed that this form of treatment had been misrepresented by Professor Osler and others, as he had never held the opinion that the eliminative and antiseptic plan could rid such organs as the liver and spleen of the bacilli lodged in them. When once the typhoid germ gains access to the alimentary tract, its multiplication occurs with extreme rapidity and the intestinal contents teem with countless numbers of them. These are not confined to the intestine, but are to be found in almost every organ of the body. He is of the opinion that the draining of the intestinal walls, following upon the action of a purgative such as calomel and magnesium sulphate, would tend to get rid of some of these bacilli in the intestinal walls, but would not effect their exit from the liver, etc. In many instances he thought the treatment had been imperfectly applied without a clear conception of the underlying principle. Under this plan Dr. Thistle has never had a fatal case of hemorrhage, whatever hemorrhage occurred having been always very slight. He has also had few perforations. Twenty per cent. of the death-rate is from perforation and hemorrhage. In Toronto this plan of treatment is universally adopted. Statistics at the Toronto General Hospital show that from 1893 until the present time there have been 833 cases in that institution with 56 deaths —a mortality of 6½ per cent. under this plan of treatment.

In discussing the paper, Dr. McPhedran of Toronto stated that he had watched Dr. Thistle's work from the time of the appearance of his first paper on the subject, but could not agree with all his conclusions. He did not think that it lessened diarrhea, tympanites, fever or delirium. He considered that Dr. Thistle was harboring the idea that purgatives in typhoid was a new discovery with him; this was not so. Twenty-five years ago he gave these for the first ten days at least. In addition to this he used to give carbolic acid and iodine, and in a certain class of cases he thought he had used the exact treatment. Another class would then come along, in which that treatment had no effect whatever. He considered that the general toxemia that existed could not be eliminated through the bowel. It

had to be done through the kidneys and skin. In reply Dr. Thistle emphasized the fact that he was not trying to eliminate bacilli and toxins from the glands, but that in clearing out the bowels he was trying to eliminate toxins and not bacilli from the body.

Sarcoma of the Right Nasal Fossa.—This paper was presented by Dr. Perry G. Goldsmith of Belleville, Ont. The patient was a man, thirty-eight years of age, a farmer, with an unimportant family and personal history. He consulted the doctor on August 4th in regard to severe frontal headache. Growths and some bone was removed from the nose. After this the swelling and pain in the eye rapidly increased, so that it was seen to project far forward, downward and outward. The growths in the nasal fossa were curetted and sent to Professor Anderson of the Trinity Medical College Pathological Laboratory, who pronounced them of sarcomatous nature, of small round-celled variety, with the walls of the blood-vessels thin and poorly developed. The discharge from the nostril was of an odor similar to that emanating from cancer of the uterus. Up to ten years ago Bosworth had collected forty of these cases. Dr. R. A. Reeve, Toronto, stated that a number of years ago he had presented before the Association a paper on the same subject. He directed attention to the importance of examining the naso-pharynx in diseases of the orbit. He cited a case similar to Dr. Goldsmith's. In his case there was little pain, but an examination of the nose revealed the tumor.

President's Address.—The hall was well filled on the afternoon of the second day when the president, Dr. R. W. Powell, arose to deliver the annual presidential address. He recited a few reminiscences when on former occasions the Canadian Medical Association had met in the Capital City in 1871, 1881, 1889, and 1893. Reference was made to the South African war in order to show the unsatisfactory condition of affairs which permitted other colonial surgeons to practise their profession in that land without hindrance, whilst Canadians were debarred from the same privilege. An earnest and united effort on the part of the profession throughout the entire Dominion of Canada in an endeavor to bring about interprovincial registration would facilitate matters in the direction of securing these privileges for Canadian professions in other parts of the British Empire. The hackneyed subject of tuberculosis was lightly touched on; whilst a very important matter relating to the profession, that of a medical defence association, was dealt with at considerable length. Dr. Powell favored the formation of such association, and later on in the proceedings nominated a committee to look into the question and report on the advisability and practicability of forming a Dominion association of this character.

Experiences in the South African War.—Dr. G. S. Ryerson addressed the gathering on the above subject. He dealt first upon the experience gained with the modern bullets. The very latest returns show that 936 officers and 11,701 non-commissioned officers and men had been wounded, of whom only 732 have died of wounds received in action, which is ascribed to the septic character of the bullet and the prompt attention and antiseptic treatment. Dr. Ryerson then described the nature of the wounds received. Referring to the reported use of poisoned bullets, this was not the truth, as the tarnish or verdigris probably accumulated in transit through the barrel. He also doubted the fact of explosive bullets being used. The Boers made use of thousands of the Martini-Henry, a heavy bullet, which caused great destruction of soft parts necessitating amputation. There were few amputations in this war. Kendal Franks performed but 20 amputations in 2000 cases. Whilst abdominal section in wounds of the abdomen was mainly inadvisable, he saw one case where the results were excellent. He spoke highly of the magnificent work of the Royal Army Medical Corps. Dr. Roddick spoke of the sacrifices of Dr. Ryerson in proceeding to South Africa at his own expense to carry out the work of the Red Cross Association. While in England recently he made it his special business to enquire of returning Canadian soldiers as to the hospital management in South Africa, and although he had spoken to many of these, he had failed completely to find a single Canadian who had anything but praise for the hospital arrangements in that country.

Our Race and Consumption.—Sir James Grant, Ottawa, considered it an important fact and one worthy of consideration that races had been born on this continent, lived and entirely disappeared, leaving mounds in the West and other traces in Florida and elsewhere of their undoubted existence. Thus far there is no information as to the exact cause of the disappearance of these races. It remains for the Anglo-Saxons to see whether they will prove more successful than their predecessors in establishing themselves on this continent. He referred to the loss of 3000 lives in the fair province of Ontario in 1898 by consumption alone, and deplored the fact that the people were not as yet alive to their danger. Sir James endorsed the legislation at the last session of the provincial parliament designed for the purpose of assisting municipalities in the erection and maintenance of sanitoria for consumptives.

Tabes Dorsalis.—Owing to the unavoidable absence of Dr. Allen McLane Hamilton, New York, through illness, the President read this paper. Looking back over a number of years, the writer finds that most good has been done where little or no medicine has been given. He has found rest by suspension and persistent cauterization of the back good treatment. Syphilis cannot be traced in more than fifty per cent. of the cases.

The Physician's "Vaster Empire."—The subject matter of this paper read by Dr. John Hunter, Toronto, dealt with the questions of sanitary science, education, social purity and medical mis-

sions. As regards sanitary science the purport of the paper was a plea for the broader and freer attainment of principles of sanitary science and their application in the building and constructions of our homes, schools, churches, etc. No dwelling-house should be constructed except under the supervision of an architect and a physician versed in sanitary science. In the matter of sanitary science, architects had improved wonderfully in the past ten years. Another important question was that of our educational system —the mental and physical health and development of school children. The best way to secure physical vigor and high mentality was surely within the province of the physician to grapple with and study. In all forms of social purity and impurity, physicians should speak *ex cathedra* against every form of vice and immorality The boys and the girls of the family should be enlightened, by the fathers and mothers respectively, as to their sexual proclivities at proper periods. In medical missions, he referred to the vast field for medical missionary work in foreign countries.

Tuberculous Lesions.—At the evening session of the first day, before a crowded assembly hall, Mr. Edmund Owen, London, delivered the "Address in Surgery." At the very outset he stated that his remarks would deal with tuberculous lesions as the surgeon meets them day by day in the hospital ward, in private practice and in the operating-theater. Discussing the origin of the word clinical, *cline,* a couch or bier—and if a bier, why not a mortuary table, he referred to the pathologist, saying he considered his (the pathologist's) thought to be only of the dead tissue. The surgeon sees the human tree during its life but rarely follows it after death. The student does clinical and pathological work at different times and he is enabled to follow the case straight from the ward to the laboratory. Study of the fresh specimen is best; for the specimen taken from formalin is no more like the condition than canned salmon is like fresh-run fish. He would not hinder experimental research work; it is absolutely essential. The life of a man is of more value than a sparrow or many guinea-pigs. It would be almost impossible to overestimate the direct value of experimental laboratory work. Strumous and scrofulous are terms devoid of meaning and we now call tubercle by its proper name. There are three great factors in connection with tuberculosis which the public must be made acquainted with, *viz.*, (1) the disease is communicable, but they must be allowed a little time before they accept this statement and fact; (2) the disease is preventable; this follows almost as a corollary to the first statement; (3) the disease is curable.

Excision of the Knee Joint.—Dr. A. Primrose, Toronto, described Kocher's method of dealing with tuberculous knee-joint and recited the histories of a few cases in which he had obtained excellent results. The operation was made clear by blackboard illustration. At the conclusion of the demonstration Dr. Primrose was highly complimented by Mr. Owen.

Recent Pathologic Studies of the Blood.—Dr. L. H. Warner, Brooklyn, contributed a paper on this subject. He premised his statements by asserting that there was a necessity for experiments for the progress of pathology. His experimental researches were directed along three lines of enquiry, *viz.*, experiments, observation and individual observation at clinics in hospitals. The examination of the blood in most cases is of more importance than the examination of the urine. Dr. Warner gave the formula of a new staining solution which he had found very practicable. The blood specimen should be prepared in the usual manner. The slides are heated in a hot oven to 98° F., immersed for one minute in a one-per-cent. aqueous solution of methylene blue, washed in water, then in one-per-cent. alcoholic solution of eosin, washed again with water, and then in a one-per-cent. solution of Bismarck brown.

The Treatment of Hernia.—Dr. F. J. Shepherd, Montreal, said it is now some twenty years since surgeons began to do these operations by the open method. The methods of operation are almost as numerous as surgeons, but there are certain general principles underlying all operations: (1) The necessity for excision or obliteration of the sac; (2) closure of canal; and (3) union by first intention. Some also hold that alteration in the direction of the canal is necessary. Bassini's is the operation performed by Dr. Shepherd, although not always successful. Absorbable sutures are the best and if antiseptic they are to be preferred. A suture that will last for three weeks is all that is wanted. He has now used chromicized catgut for some time. He never washes out the wound and thinks it better to dissect out the sac with the knife than to tear it with the fingers. He never uses a drain. For the last two years he has used rubber gloves in all his surgical work on the abdomen and he considers his results have been better since he used them. In these operations the mortality is practically *nil.* Operations on children are now our most successful cases. Formerly they were not advised except when strangulation existed. In discussing this paper and the cases recited, Dr. Lapthorn Smith stated that his experience lay mostly in ventral and umbilical hernias, some of them being so large as to require twenty stitches. During the past two years he has abandoned silk and resorted to catgut, chromicized, which he always prepares himself.

Dr. Shepherd in reply said if there is a little oozing in the wound, he introduces between the edges of the wound a probe and lets out the accumulated serum, and he finds that this is quite efficacious, as by this method the chance of any germs entering is minimized.

Syphilitic Gummata of the Spinal Cord.—This case, reported by Dr. F. W. Campbell of Montreal, was a very interesting one. The patient was a highly neurotic individual and some time

before had suffered from insomnia of an aggravated character. Retention of urine and loss of power in the lower limbs were noted. The patellar reflex was about normal. The loss of power in the lower limbs was absolute. The pulse varied from 80 to 96; the temperature never rose above 99° F. The stomach remained in fairly good condition all the time. A consultant from New York was brought on and a diagnosis was established of tumor which might be sarcomatous or syphilitic, of the spinal cord situated about the first lumbar vertebra. The advice of the consultant was to give 500 grains of iodide of potash per day, at first commencing with one dram three times a day. Dr. Campbell recited the daily history of the patient while getting under the large dose and its gradual withdrawal. The patient is alive to-day and in good health, having recovered complete control of his lower extremities.

Address in Gynecology.—Dr. Wm. Gardner of Montreal delivered a very practical address upon the mistakes in diagnosis and treatment in midwifery and gynecology. We often learn more from our mistakes than from our successes. Correct and accurate diagnosis depends mainly upon a sense of touch which is only to be attained by long and patient practice. The advantages of examining on a firm table instead of on a couch or bed were emphasized. The patient's rectum should always have been emptied before presenting for examination. It is best to empty the bladder by catheter when the patient is in position, as it is in this way that you will notice any discharges, etc., and an uncontaminated specimen for examination is thus obtained. Where tension is present in the muscles of the abdomen, if you make a series of circular movements over the lower abdomen, gradually narrowing your circle, you will be able to overcome whatever rigidity may be present. In physical examination Professor Gardner urged caution in the use of the sound. In pelvic examinations he has made it a point to examine the position of the kidneys as well. In the diagnosis of pregnancy mistakes are often made. The patients are few in whom the diagnosis cannot be made by careful examination of history, signs, etc. Many women are probably inaccurate as to date. Dr. Gardner illustrated all his points by reciting cases to the point. He instanced one in particular where he once found a woman in his office on her hands and knees in the throes of a twin labor, a fellow practitioner having failed to recognize the pregnancy had tapped the gravid uterus and drawn off a considerable quantity of liquor amnii. The paper closed with an interesting account of mistakes in extra-uterine pregnancy.

Abdominal and Pelvic Disturbances in Women.—Dr. Clarence Webster of Chicago in this paper spoke of symptomatology in women often overlooked by the general practitioner. He then took up the normal relationship of the abdominal and pelvic contents and proceeded to account for intra-abdominal pressure, the pelvic organs being to a great extent maintained in their respective positions by reason of the pressure of the abdominal and pelvic walls. The average specific gravity of the viscera was very little more than that of water; that of the liver was 1.5. There is no proof that the mesenteries act as constant supports or were ever meant to be such; and the main factor in sustaining the viscera is the strength of the abdominal wall and pelvic floor. Local weakness of the abdominal wall has been fairly well described under hernia while general weakness of the abdominal wall has been described as pendulous belly; and general weakness is an exceedingly rare condition. As to the question of etiology, the condition is found in women who have borne children; on examination of the great majority of women, there is some degree of separation of the recti muscles in the region of the navel. All evidence later on may disappear but permanent widening remains. The results of all this is unavoidable enteroptosis; and it is generally to be found in women who have worn corsets. A common displacement is that of the right kidney. Dr. Webster dwelt upon the diagnostic symptoms of these conditions and then proceeded to describe the operation he performs for their relief. This consists in bringing the edges of the two recti into apposition. He first performed an operation for the relief of the condition in November, 1898, and since that time 41 cases have been operated on and the results have been most satisfactory.

Address in Medicine.—The advance in knowledge, said Prof. Frederick C. Shattuck of Boston, in his opening remarks, has brought about our relation to things. There is noticed a subdivision of labor in every branch of industry. Specialization has taken place in the science and art of medicine. In specialization lies the cleavage between medicine and surgery; and nowhere has the line been more closely drawn than in England. Anesthesia greatly enlarged the bounds of surgery. Twenty-five years ago there was not a pure surgeon in America. Belly-ache is now a surgical disease. The heart is practically the only viscus which remains the exclusive organ of the physician. In this country the general practitioner is clinging to obstetrics for family practice. In some of the larger centers there is a tendency to the specialist in obstetrics, who will preside at the accouchement and the family physician then step in as attendant throughout the puerperium. Pure gynecology scarcely exists today; and pelvic tinkering is suffering a rapid decline. The great bulk of major gynecology belongs to abdominal surgery which in turn belongs to the general surgeon. Gynecologists should study general surgery and become general surgeons first. The field in medicine is so large that no man can grasp it all in a lifetime. Professor Shattuck referred to specialism in neurology and dermatology. Nose and throat should comprise one specialty. Desire on the part of some to escape the hurly-burly of general practice may be a cause in throwing them into

specialism; and then special knowledge draws larger fees. Ophthalmologists get more for removing a speck of dust from the eye than the general practitioner. When we have specialists for the diseases of young life, why not also have a specialty for the disease of old age. Professor Shattuck closed his able address by affirming that specialism in medicine had come to stay.

Gastric Hemorrhage.—Dr. George E. Armstrong of Montreal, in reading this paper, stated there was a fairly well-determined field in which surgical interference may be of use in hemorrhage of the stomach. Hemorrhage occurs in fifty per cent. of gastric ulcers and is fatal in eight per cent. These cases are arranged in two groups, the acute and the chronic. Rodman has reported 31 operations for frequently recurring or chronic hemorrhages with 6 deaths. Dr. Armstrong has operated five times for gastric hemorrhage, one being a chronic case. In one of these cases the patient was getting along nicely after the operation, when the patient expired suddenly and on post-mortem examination thrombi were found in the branches of the pulmonary artery.

Uterine Retroversion and Prolapse.—Dr. A. Lapthorn Smith of Montreal referred to the proper and most successful management of procidentia uteri in elderly women between seventy and seventy-five years of age. The majority of these patients have an ulcerated cervix. After confinement the uterus remained enlarged and the pernicious habit of keeping women too long on their backs has a tendency to produce backward displacement. Dr. Smith feels certain that women who have been cured of this distressing condition will have little difficulty in persuading others to avail themselves of the treatment. In correcting this deformity, Dr. Smith makes a small incision in the abdomen and performs ventrofixation. After that the vaginal canal is narrowed by a large anterior and posterior colporrhaphy. In selected cases he also amputates the lower half of the organ and stitches the vagina to the upper half. He considers ventrofixation, if properly performed, a most reliable means of fastening up the uterus. The operation has given him the most complete satisfaction of any he has ever performed, especially when combined with amputation of the cervix and posterior colporrhapy.

Gasoline as a Surgical Detergent.—Dr. Bruce, Toronto, contributed something highly original, that is, the use of gasoline for cleansing dirty, greasy hands and for preparing the field of operation before surgical procedures. It is much better than soap and water and brushes; and he now constantly carries a small bottle of the substance in his surgical bag. A report from Dr. Wm. Goldie, Toronto, showed its effects upon germs and germ life. A word of caution is to be borne in mind; as it is a highly inflammable substance, it should not be used in any quantity near an exposed light; moreover, it is painful when applied to the eyes or ears. It is useful in cleansing sutures of accumulated blood and dressing powder, as it enables one to locate the stitches better. Dr. J. C. Mitchell, Enniskillen, Ont., stated that he had tried gasoline recently as a detergent in two very severe threshing-machine accidents, where the parts were covered with oil and grease and dirt, it was very satisfactory, as he was able to get perfect cleanliness and both wounds healed by first intention.

Dilatation and Prolapse of the Stomach.—A paper with the above title, contributed by Professor McPhedran of Toronto, dealt principally with prolapse. This condition rarely occurs alone, but is associated with prolapse of other abdominal organs. There is generally present, as well, some degree of dilatation; the abdomen may be prominent or flat or even retracted. He related the case of a man, aged 51 years, a manufacturer, who had been ailing for two or three years. The stomach was below the umbilicus. He was directed to massage the abdomen very thoroughly and to practise abdominal gymnastics. Through this treatment combined with dietetics, he has been restored to health and is able to resume business. Another case of a woman, aged thirty-five years, who had been the subject of recurrent attacks of vomiting for two years. The symptoms were detailed; massage and abdominal gymnastics ordered with satisfactory results. The different ways of examining the stomach were described; and in concluding Dr. McPhedran spoke of the benefits of a change of scene in treating these cases.

Physical Training.—Dr. B. E. McKenzie, Toronto, gave a very interesting account of the methods employed by him in correcting deformities in his orthopedic hospital in the city of Toronto. The paper was illustrated by lithographs showing improvements in spinal deformities and other abnormalities. The paper embraced the results of his observations for thirteen years past, and was ample justification of the benefits derived from gymnastics in the correction of lateral curvature, clubfeet, etc. He had found physical training also especially valuable in hysteria and chorea.

Inter-Provincial Registration.—Dr. T. G. Roddick, Montreal, read the report of the Committee having this matter in hand. A new feature was that allowing of representation on the proposed Dominion Council of homeopaths, as, according to the law of Ontario, these had their vested rights and so must have similar interest in any Dominion Council. The homeopaths, then, will be allowed three representatives, which will be equivalent to the representation from any one province of the Dominion. Their term of office will be four years. This will not, however, be inserted in the bill as such, but will appear under "any other school of medicine having legal recognition throughout Canada," as the British Medical Council would not recognize any such body. Dr. Roddick stated that the bill would be introduced at the next session of parliament; and that the respective members of the Committee must bestir themselves before their respective provin-

cial parliaments, as these must sanction the measure before it could be finally acted upon by the Dominion parliament.

Cerebral Abscess.—Dr. James Stewart, Montreal, reported two interesting cases of abscess of the brain situated in the tempero-sphenoidal lobe, and referred to the usual existing aphasia which was present in both of these cases, *viz.*, simple ability to name objects. The first case occurred in a young man, twenty-two years of age, who had otitis media following an attack of influenza. Some six weeks afterward an abscess formed. The abscess was diagnosed as confined to this area simply on account of the peculiar aphasia, the simple inability to give the name of a pen when that object was presented to him. The patient was operated on by Professor Bell who secured two ounces of pus. Meningitis, however, set in and the patient succumbed. The second case was a girl twenty-one years of age. She had had ear trouble for a great many years with very severe pain at times. She, too, had difficulty in naming objects and finally she could not name any object whatever. She died suddenly a few hours before the operation was to be performed. On post-mortem two abscesses were found, one skirting the upper border of the lobe and the other about the center of its substance. In reply to a question of the President Dr. Stewart stated there is what is called the naming center and when this is destroyed that particular form of speech defect is present. The cases were aptly illustrated by a diagram.

Gangrene of the Leg Following Typhoid Fever.—Dr. H. H. Chown, Winnipeg, reported two cases of gangrene following an attack of typhoid fever which had recently come under his observation. In the first case the patient had the classical symptoms of typhoid, the spots appearing at the end of the first week and being very numerous. Great pain set in in the calf of the leg, with collapse, while the limb was cold and bloodless. Cutaneous sensibility was lost over the leg. The third day after the complication set in, the part involved included the lower third of the leg on the inner and lower half on the outer side. Operation was performed at the upper and middle third of femur. Patient stood the operation well. The temperature before the operation was 102.6° F., pulse, 120; on the following day the temperature was normal and the pulse 110. On the tenth day the flaps were united. There was a rise of temperature a few days later—a relapse, with hypostatic congestion of the lungs. On the fifth day hemorrhage of the bowels. The patient is now a picture of health, weighing 200 pounds. The second was a somewhat similar case in which the blood reacted early and promptly to the Widal test. The gangrene began in the first case on the eleventh day of the disease; in the second on the ninth. Keen reports gangrene on the fourteenth day. The gangrene in the second case extended to the upper and middle third of the leg. The leg was amputated and prompt union took place throughout. In discussing the cases, Dr. R. B. Nevitt, Toronto, mentioned a similar case coming under his observation during the past summer. Here gangrene occurred about the third week of the fever, and the patient was seen about a week or ten days afterward. Amputation was performed through the middle third of the femur. He also referred to a case of gangrene of the arm following an attack of pneumonia recently observed by him.

Notes on Atropine—Dr. R. D. Rudolf, Toronto, read an interesting paper with the above title, illustrating by means of a chart the action of the drug on animals and inferences drawn therefrom of its therapeutic uses. He finds that the drug directly stimulates the heart, and thus the blood-pressure is markedly raised. He considers that the maximum single dose of 1/20 of a grain, as laid down by Witherstine, is too large unless used as an antidote; and one ought never to give more than 1/100th of atropine sulphate at one time except in emergencies. He also referred to its action in catarrhal pneumonias of children and its employment before anesthesia to ward off danger. Dr. A. D. Blackader, Montreal, discussed the paper and congratulated Dr. Rudolf upon it and hoped that he would pursue his studies further upon the same subject to find out the effect the drug would produce in controlling vomiting after anesthesia. He considers, however, that strychnine and not atropine is the most powerful heart tonic we possess. He thought that late experiments would throw doubt upon atropine being a direct stimulant to the heart muscle; and he thought it questionable to administer a drug that will paralyze nerve-endings when we want to stimulate the heart's action.

Lantern Slide Demonstration of Skin Diseases.—Dr. George H. Fox, New York, conducted this demonstration which the members of the Association appreciated most highly. The great majority of the skin lesions shown were of syphilitic origin, and as they appeared on the canvas Dr. Fox described the histories of the cases. One in particular attracted attention from the disfigurement of the nose and face—a huge mass of excrescences, which Dr. Fox was able to get rid of in the course of two or three months, leaving only a slight superficial scar. He laid down a timely word of caution in treating these conditions, that when the patient was run down and emaciated through large doses of mercury or iodide of potash, not to keep on pushing these drugs, but to desist for a period and endeavor to build up the patient's general condition, and then return to the specific treatment and the results would be found to be more material. At the conclusion of the demonstration, which will rank as one of the features of the meeting, Dr. Fox was accorded a hearty vote of thanks by the Association.

Nerve Suture.—Dr. F. J. Shepherd showed an interesting case, a boy of sixteen, who at the age of six sustained a severe cutting of the nerves

of the brachial plexus below the cords of the brachial plexus. At that time, ten years ago, Dr. Shepherd dissected out each nerve and united their respective ends by suture. All did well with the exception of the musculo-spiral, and as a consequence the lad has very little control over the extensors of the forearm.

Systemic Treatment of Disease of the Eyes.—Dr. George H. Burnham's method of treating syphilitic and other diseases of the eye is to combine the hypodermatic use of pilocarpine with the administration of the usual remedies. Under this method no such result follows in other plans of treatment, and with this a permanent curative result is got. The treatment has a wide application. Whether iodide of potash and mercury or the iodide alone is given internally in suitable cases without satisfactory results, if the pilocarpine be added, good results will follow.

Mental Sanitation.—Dr. R. W. Bruce Smith, physician to the Brockville Asylum for the Insane, contributed a scientific paper with the above title. It was a plea for prophylaxis in insanity, and he thought that much would be accomplished in this direction in the twentieth century. He stated that insanity is on the increase in Canada and thinks it can be duly ascribed to the fact that there have been no preventive measures employed. In order to accomplish good in this direction we must seek either to lessen the demands on or to strengthen the resisting power of the brain. He condemned intermarriages in families and also amongst those of a deranged mentality; and as fifty per cent. of the cases of insanity are heredity, the descendants of these should be careful in contracting marriage-ties. He referred to a portion of one county in Ontario alone where indiscriminate marriage and intermarriage have become most fruitful of insanity; and he has seen several members of one family from that locality inmates of the same institution at the same time. He considers that the day may yet dawn when we will give the same attention to the rearing of children as we now give to the breeding of horses. Speaking of farm-life and the tendency it has to melancholy, he thought this class of the community should receive education in participating more in the enjoyments of life and not continue to rot in domesticity. An upheaval in the sentiment and surroundings of the rural homes would work wonders in prophylaxis principles.

Election of Officers.—The following officers were elected: President, H. H. Chown, Winnipeg; Treasurer, H. B. Small, Ottawa; General Secretary, F. N. G. Starr, Toronto.

Winnipeg was chosen as the next place of meeting.

REVIEWS.[1]

Surgical Pathology and Therapeutics. By John Collins Warren, M.D., LL.D., Professor of Surgery in Harvard University; Surgeon to the Massachusetts General Hospital. Illustrated. Second edition with an appendix containing an enumeration of the scientific aids to surgical diagnosis, together with a series of sections on regional bacteriology. Philadelphia: W. B. Saunders, 1900.

The appearance of a second edition of this justly popular work is to be noted with pleasure. Though the field of pathology is well occupied by such an endless array of text-books and manuals that to stand in the front rank requires more than ordinary merit, it is not going too far to claim for the present volume a place among the foremost. Features perhaps that have contributed to its popularity are the judicious combination of therapeutics and morbid anatomy and the incorporation of the line of treatment to be pursued with the description of each pathological entity. Coming from so distinguished an authority these discussions are of the greatest value and contain much that is interesting and suggestive to the specialist as well as to the student or general practitioner.

In this edition the author has embodied the important changes in an appendix which replaces the old one and the chapter on antiseptic surgery. Under the heading of "Scientific Aids to Surgical Diagnosis" he enumerates the more recent methods which may serve as short cuts to diagnosis and gives in addition a series of articles on what may be termed regional bacteriology. The various vegetable parasites liable to be found in different portions of the body, such as the peritoneum, the genito-urinary tract, the mouth, etc., are described, their characteristics noted and suitable methods for their recognition, identification and extermination indicated.

The illustrations, so essential a factor in the value of a book dealing with this branch, leave little to be desired and in many instances offer striking evidence of the recent advances in color printing, although the author, especially in the sections on tumors, has not always resisted the temptation to portray exaggerated and bizarre cases rather than what is typical of everyday practice.

Mikroskopie und Chemie am Krankenbett. Für Studirende und Aerzte. Bearbeitet von Dr. Hermann Lenhartz, Professor der Medicin und Krankenhaus-Direktor in Hamburg. Dritte wesentlich umgearbeitete Auflage. Berlin: Julius Springer, 1900.

In this little volume the whole subject of clinical microscopy and chemistry is adequately yet succinctly discussed. After an introductory chapter on the manipulation of the microscope the

first section is devoted to the consideration of the animal and vegetable parasites occurring in the body in health and disease. Nearly twice as much space is given to the latter as to the fomer, the general principles of bacteriological technic being first briefly described, special methods of staining and culture receiving treatment *in extenso* under the headings of the various specific micro-organisms. This is followed by a section on the blood which sufficiently covers the field of pathology and diagnosis, and by another on the examination of the expectoration which is most praiseworthy in its thoroughness. In Part IV. the investigation of the secretions of the mouth, stomach-contents and feces is described while by far the largest portion of the book, comprising nearly one hundred pages, is given up to the subject of urinalysis. The sixth and last section embraces the microscopy and chemistry of exudates, transudates and the contents of cysts of various descriptions.

In point of conciseness and clearness nothing is left to be desired, while a sufficient variety of methods and formulæ is given to make the book a useful and complete laboratory guide. In this, the third, edition, the text has been fully revised and numerous additional illustrations have been interpolated.

A Text-Book of Practical Therapeutics. With Especial Reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. By Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. With special chapters by Drs. G. E. de Schweinitz, Edward Martin and Barton C. Hirst. New (8th) edition. Philadelphia and New York: Lea Brothers & Co., 1900.

The appearance of eight editions of a book within nine years means merit of more than an ordinary order and the fact that the present volume has reached this distinction is a sufficient index of its value and the general appreciation it has met. In the present edition no change has been made in the arrangement of the subject matter which is still divided into two main parts, drugs and diseases. In the former there is presented for each remedial agent of accepted utility an adequate and essentially up-to-date *résumé of* its physiological action and therapeutics, the author condensing into a few paragraphs the conclusions of all the observers whose work has bearing on the subject and giving the facts in a nutshell. The section on diseases is no less valuable and at a glance one may run over the different methods of treatment available for any particular affection and select the most appropriate. The value of the work for quick reference is greatly enhanced by the very complete system of cross-indexing. In its new form the text has undergone revision and been made to conform not only to the United States Pharmacopœia, as it has done, but also to the British Pharmacopœia of June, 1898. Some articles on new drugs have been added and also several illustrations; the most notable picture in the book is a full-page colored plate depicting in glowing colors five roosters' heads and intended to illustrate the action of ergot, which, however interesting it may be from a poultry fancier's point of view, or as a monument of modern lithographic skill, seems a trifle out of keeping with the very practical tone of the book in general.

Fractures and Dislocations of the Upper Extremity. By T. E. Platt, M.D., F.R.C.S. London: H. K. Lewis, 1899.

To quote the author's own words in the preface, this book is "almost entirely a reprint of a series of papers contributed to the *Medical Chronicle*, 1898." The work certainly gives evidence of painstaking records, a wide familiarity with literature, and the data from its statistics bear out all that has been maintained in special works on the subject, but nothing beyond this. A liberal reference and a free criticism of the methods of treatment, and of the mechanism of fractures is current throughout these pages, yet there is nothing of an experimental nature or practical application to substantiate the ground taken, only the tried and trusted having been applied. The one novel feature are the skiagrams, but poorly reproduced, and they in some few instances illustrate what the author maintains, that for personal inspection skiascopy is more satisfactory as it offers a kaleidoscopic view, whereas for illustration, several skiagrams from different points of view are necessary and these must be contrasted with skiagrams of the sound members.

This style of book can only appeal to those specially interested in this class of injuries.

Fractures. With an Appendix on the Practical use of the Röntgen Rays. By Carl Beck, M.D., Visiting Surgeon to St. Mark's Hospital and to the New York German Poliklinik; Formerly Professor of Surgery, New York School of Clinical Medicine; Consulting Surgeon to Sheltering Guardian Society Orphan Asylum, etc. Philadelphia: W. B. Saunders & Co., 1900.

The dedication of this book is a light upon its tenor and spirit, "To Wilhelm Conrad Röntgen, Without Whose Discovery Much of This Book Could Not Have Been Written", that is to say, it aims very directly to show the value, application, errors and deficiencies of the X-ray.

The other features of the book are of a high order and reliable in their doctrine. The appendix on the practical use of the Röntgen rays contains much information of great value born of close reading, careful experimenting and judicious interpretation. The book is well worthy of a place among the surgical works of our libraries.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVII. NEW YORK, SATURDAY, SEPTEMBER 29, 1900. NO. 13.

ORIGINAL ARTICLES.

MEDICINE AND SUPERSTITION.[1]

By G. W. GUTHRIE, M.D.,

OF WILKES-BARRE, PA.;

PRESIDENT OF THE PENNSYLVANIA STATE MEDICAL SOCIETY.

ONCE before, on the 13th day of June, 1866, thirty-four years ago, your honorable body assembled here in annual session. The records of that meeting are very interesting, when compared with the proceedings of your later sessions.

The place of meeting was in a hall over a furniture store, entered from an alley, and not much longer than the room now belonging to the Luzerne County Medical Society. The total attendance, including delegates and permanent members, was sixty-seven, to which were added the names of nine members of the local county society, not delegates. The entire membership of the Luzerne County Medical Society, which then included Lackawanna, was twenty. Of the delegates from the county, not one is in practice and only one, Dr. A. L. Cressler, is living. But what changes thirty-four years have wrought! The borough of 1866, with less than 10,000 people, has become a city of over 51,000 within its borders, and a suburban population of an equal number. The county has been divided and each division represents an active medical society, and their combined membership reaches one hundred and seventy-five. From an attendance of sixty-seven, your later sessions have had anywhere from two hundred and fifty to four hundred members present.

One moment let me pause for a thought of those—"lost to sight, to memory dear"—who have been called to their reward since last we met. Their names as far as reported are:

John Ashhurst, Jr., (1881) Philadelphia; Samuel P. Bartelson, (1879) Clifton Heights; Nathaniel W. Brown, (1890) Pittsburgh; John H. W. Chestnut, (1876) Philadelphia; Robert B. Cruice, (1879) Philadelphia; Alexander Craig, (1869) Columbia; Milton S. Erdman, (1894) Richland Center; Quintus C. Farquhar, (1882) California; Albert Fricke, (1862) Philadelphia; Robert G. Furst, (1896) Lock Haven; Robert M. Girvin, (1880) Philadelphia; William B. Hartman, (1882) St. Mary's; Columbus W. Krise, (1877) Carlisle; Edward Lyon, Sr., (1871) Williamsport; James McCarrell, (1878) Allegheny; John B. McCloskey, (1899) Mill Hall; David S. Marquis, (1863) Rochester; Charles S. Shaw, (1890) Pittsburgh; S. S. Towler, (1893) Marionville; Mark G. Whittier, (1892) Clearfield.

No better tribute can we pay them than to say in the words of our doctor-poet, Weir Mitchell:

> "To give what none can measure, none can weigh,
> Simply to go where duty points the way.
> Faith, honor, duty—duty calmly done,
> That shouts no self-praise o'er a victory won;
> One bugle note their battle call,
> One single watchword, DUTY—that is all."

Dr. Dennis, in his address of welcome to you in 1866 said, "We need your help to stay the flood of medical nonsense and knavery which seems to be sweeping over the land as with a besom, with redoubled energy, deluding and destroying the weak, the ignorant, and the foolish."

These words are very fitting to-day, for "the flood of medical nonsense and knavery" has risen to an astonishing height; what with Dowieism, and Osteopathy, and Christian Science; the divine healer, the magnetic healer, the fire doctor, the powwower—the honest medical man, especially if he be young, becomes disgusted and discouraged with his fellow men, and bewails the degeneracy of the times; but to such I would say, "Say not that the former days were better than these, for thou dost not inquire wisely concerning this." The history of the human family is a history full of machinations of the quack, the sorcerer, the charlatan. Let me direct your attention briefly to a few propositions which appear easily demonstrable: (1) There is no limit to human credulity. (2) Human credulity is so great that any pretense to cure, however ridiculous, has always found adherents. (3) That a method of healing that claims to be supernatural in its power, that surrounds itself with an air of mysticism, claiming some mysterious, magnetic agency not possessed by others, has always found followers in great numbers. (4) Numbers and intelligence of followers is no evidence of the truth of a method of cure; the most ridiculous and preposterous theories and methods have had hosts of followers, often from the intelligent classes.

There is no limit to human credulity. Carlyle once said, "England has twenty millions of people, nearly all fools," and it is surprising how far this remark of the cynical old philosopher applies to humanity in general. The three most sacred interests of the human family are the immortal soul, the almighty dollar, and the conflict with disease and death: religion, finance, and medicine.

> "All hail, Religion, maid divine!
> Pardon a muse so mean as mine
> Who in her rough imperfect line
> Thus dares to name thee."

[1] Address delivered at the fiftieth annual meeting of the Pennsylvania State Medical Society, held at Wilkes-Barre, Pa., Sept. 18, 19, 20, 1900.

But what will not people believe in thy name! What blind credulity was needed to make John of Leyden possible! Did ever fanatic or imposter propose a belief too ridiculous, or too wicked to find followers?

Much as men love their souls, and their bodies, it seems at times they love their money more—but how they are fooled! I need but to refer to John Law and his Mississippi scheme, to De Lesseps and his Panama Canal Company, or to Plunger Miller; Law, who bankrupted Paris with a scheme that existed simply on paper, De Lesseps who borrowed two hundred and sixty-five million of dollars from the French people, from which there was no return, and Miller who offered ten per cent. a week, five hundred and twenty per cent. a year, for money, and got it in enormous quantities. But it is in the matters of health and sickness, in the conflict with disease and death, that the human family has shown its greatest credulity, its greatest capacity for being deceived. And here I will appeal to the logic of events by briefly recalling the facts of history, which will, I believe, serve as a complete demonstration of my remaining propositions, and it shall be my purpose in this discussion to be entirely just and to

> "Nothing extenuate,
> Nor set down aught in malice."

Nor shall it be my purpose to inveigh against any so-called medical sects who are practising under legitimate conditions. For myself I see no justification for medical sectarianism; all honest investigators, all men liberally educated along medical lines, embracing the fundamental branches of medical education: anatomy, physiology, chemistry, therapeutics, pathology, bacteriology, surgery, and the practice of medicine—all these ought to be united under one banner in the contention against charlatanry, quackery, and deception of every kind. The establishment of State Boards of Medical Examiners, and State Boards of Health, where men of different faiths are cooperating, have a tendency to this end. The size of a dose of medicine is a little thing upon which to split, and retaining a distinctive sectarian title as a trade mark is certainly not becoming honest, scientific investigators.

First then let us momentarily consider Relics, Shrines, Apparitions—agencies supposed to be supernatural and religious in their character. Pettigrew says that to the people "Whatever is beyond their sagacity is assigned to invisible agency." In all ages, even at the present time, people have rushed in hordes to be healed by some relic of a saint, or where some apparition has been observed, or to some holy well or fountain, and, no doubt numbers have gone away relieved; stacks of crutches, and other evidences of cure left behind substantiate this statement, for under the influence of a strong, devout, religious impression, many ailments, functional or nervous in their character, have been relieved. But it is a source of the greatest gratification to the profession that the clergy of whatever name, are as a class, adherents of the true medical faith. Sorry it is that there are exceptions to this rule, that now and then we see the name of a person with the title "Reverend" quoted as subscribing to the virtues of some quack nostrum, or upholding some medical delusion—as osteopathy for example. But do we not also find occasionally a name bearing the title of M.D. associated with the same delusion, as when a doctor so far forgets his birthright as to become an adherent of Christian science or osteopathy? But, I repeat, that the great and noble army of religious teachers are with us and depend upon us in the time of their physical troubles, and you will bear me out in the statement that we have no more loyal, more devoted, more grateful adherents than they. Nor can we forget that we owe to a clergyman the most touching tribute ever paid to the medical profession; the character of Weelum MacLure, the Doctor of the Old School, as portrayed by the Rev. John Watson, Ian MacLaren.

The same superstitious reverence makes people believe in charms and amulets. The fire doctor, who takes fire out of a burn by blowing his breath upon it and murmuring some incantation, or the old woman who looks at the moon, and mumbling some unintelligible words, takes the warts from children's hands, are with us still. Amulets suspended from the neck, as bags containing sulphur or asafetida, are still worn to keep disease away; and the horse chestnut is carried for hemorrhoids, and the iron ring is worn for rheumatism.

History is loaded with the records of cures by these agencies, and there is scarcely a malady that has not had its cure. The charms that were most effective were those having something of the horrible associated with them—such as coffin nails, a bit of hangman's rope, chips from a gallows, spiders suspended from the neck, arsenic, or pieces of dried toad applied over the heart.

Another far-reaching delusion was the Royal Touch for Scrofula. So prevalent was this delusion at one time that the name "The King's Evil" was given the affection. The King who ruled by the grace of God would naturally be supposed to possess divine power. From the time of Edward the Confessor to the reign of Queen Anne, a period of seven hundred years, this belief prevailed.

One method was this: The patient obtained from his physician a certificate of diagnosis, or a statement that the patient was suffering from scrofula; then on certain days the sovereign would lay his hands on them, and at the same time give them a piece of money, usually of gold. Pettigrew says that during the reign of Charles II., in twenty years, from 1662 to 1682, no fewer than 92,107 persons were touched, and he further states that during this reign "more people died of scrofula than during any other period." A record is in existence, made as late

as March 30, 1714, during the reign of Queen Anne, showing her majesty on that date touched 200 persons for "the evil," among them the great lexicographer, Dr. Samuel Johnson, who was then four and a half years old. To show how groundless was this belief we have only to recall that this truly great man suffered from scrofula during his entire life.

But this delusion and many others have disappeared, and nought remains but royal touch pieces in museums to remind us of the credulity of the human family.

Passing by Mesmer, after whom mesmerism was named, and who claimed to cure patients with "manipulation aided by dimly lighted rooms and soft music." and Gassner, who was a cotemporary, we come to consider a delusion, originated by a fellow countryman, named Perkinism, or Elisha Perkins and his Tractors.

Perkins was born at Norwich, Conn., in 1741 He received a medical education, and for a number of years practised his profession successfully in Plainfield. In 1796 he invented his metallic tractors, which were three inches long and tapering to a point, one resembling brass, the other steel. With these he claimed he could draw diseases from the body; particularly local pains, inflammations, neuralgia of the head, face, and teeth, and rheumatism; this was done by applying the tractors over the painful parts and drawing them downward, for twenty minutes or longer. It does seem ridiculous, doesn't it? But ridiculous as it may seem, this method was recommended by the faculties of three institutions in this country; it received a favorable report from a Swedish body of investigators, consisting of twelve physicians and surgeons of the Royal Frederick Hospital; and in London a Perkins institute was founded under the presidency of Lord Rivers, which published cures to the number of 5000, certified to by eight professors, forty physicians and surgeons, and thirty clergymen. One writer says that the list of persons who claimed to have been cured by this agency amounted to an almost fabulous number. Perkins died in 1700, and in a few years the tractors fell into disfavor, and are now found only adorning museums, touching reminders that there is no limit to human credulity in matters pertaining to health and disease, and this was only one hundred years ago.

A cotemporary of Perkins was Cagliostro, the Italian charlatan. Perkins no doubt was an honest, self-deluded enthusiast, but Cagliostro was one of the most capable scoundrels the world had ever seen. He was born at Palermo in 1743, two years after Perkins. His right name was Balsamo. At the age of fifteen he ran away from school, was placed in a monastery, where he assisted the apothecary, and obtained a smattering of medicine that helped him perpetrate his future villainies.

Leaving the monastery, he traveled in almost every known country, practising the arts of healer, necromancer, nobleman, exorcist and spiritualist. In Arabia he was the guest of the Mufti of Medina, and the Sheriff of Mecca. In Malta he duped the Grand Master of the Knights of Malta, assumed the title of Count de Cagliostro, and obtained letters of introduction to the nobility in various countries of Europe. He married the beautiful Lorenza Feliciana, who aided him in his iniquities. In Germany he exhibited an elixir, which gave perpetual life and never ending beauty, claiming he was over two hundred years old, through the use of this agent. By his power as necromancer, he claimed to hold communion with celestial spirits; his victims were very numerous.

France was the theater of his greatest success for a time. Here he established "The Triumphant School of Wisdom," changed baser metal into gold, restored youth, and prolonged life indefinitely; among his disciples were the most noted members of the French Court, including Cardinal Rohan. A scandal connected with the theft of a necklace drove him from Paris after lying some time in the Bastille. His waning star failed to impress the British mind; Germany expelled him, and going back to his native Italy, he was arrested and received death sentence, which was commuted to life imprisonment, during which he died in a dungeon, in 1795, after an incarceration of eight years. But, now methinks, I hear you say, "Are we not better than they?" No, in no wise, for the nineteenth century has as many instances of medical delusions as any of its predecessors.

There was Samuel Thomson, founder of the "botanic school," who undertook to cure "all fevers, whether black, grey, green, or yellow," by decoctions of indiginous plants of the most depressing character, as lobelia; who when treating a case that was probably pneumonia, "puked the patient violently thrice." then put him to bed then puked and sweated him for three days until he was so weak he could puke no more. When Thomson asked the patient how far down the medicine had got, and the patient, indicating his chest, the quack replied that "it would soon get down and unscrew his navel." Death followed this treatment in three days, and Thomson was defendant in a suit of manslaughter, but was acquitted; this was in 1809. He had many followers, and Thomsonianism has become a name in medical history.

Time compels me to pass by a number of worthies, who in one way or another claimed great power as healers in the early years of the century, and I will come to a period nearer to our own recollection. Who has not heard of Francis Schlatter, the Divine Healer?

Francis Schlatter was an Alsatian peasant, with an ordinary education, a shoemaker by trade, who came to this country and settled in Jamesport, L. I. He had no bad habits, was a good shoemaker, paid his debts, was a glib talker, and claimed, at times, to have visions

In 1894 he turned up in New Mexico as the New Messiah, and claimed extraordinary power in curing diseases. In the summer of 1895 he went to Denver, Colo., calling himself the "New Messiah and the Healer," and from August 22 to November 13, 1895, it is stated that about 300,000 people visited him. On the last day he treated 5000 people. He left Denver, traveled south across the Rio Grande into Mexico with his mule, and went into the wilderness to fast. Some time after the newspapers contained the following dispatch: El Paso, Texas: Francis Schlatter found dead in the foot hills of Sierra Madre, S. E. of Casa Grande, State of Chihuahua, Mexico; death probably due to starvation." This simple statement of facts is more forceful, and tends more to substantiate my propositions than any additional comment I could make.

Bear with me while I speak of another Divine Healer who has been attracting a great deal of attention in another western city, Rev. John Alexander Dowie, the founder of Dowieism.

Dowie was born in Scotland fifty-five years ago, was educated in a Congregational Theological Seminary in Edinburgh. Was taken seriously ill of stomach trouble, and was told by his physician that recovery was impossible. He then sought relief in prayer, and reading the Scriptures, and claims he was instantly cured. He emigrated to Sydney, N. S. W., as a clergyman, but gradually drifted away from his church, until 1878, when he resigned. He then went to Melbourne, Australia, where he established the Free Christian Tabernacle, and taught in his own way. A little later he developed his divine healing theory. During an epidemic of fever, he went in among the afflicted, laid hands upon them, prayed, and he says, cured thousands. He also states that his fame became so great that all Australia praised his name. He came to America in 1888, landing in San Francisco, where he established missions and healed many; remained two years, and then went to Chicago. Here he established healing missions in many parts of the city, got into the courts many times, and four years ago founded a new church, named the Christian Catholic Church of Zion, calling himself the General Overseer. He has erected a tabernacle in addition to healing homes, and claims that last year 12,000 people came into his fold; and that his followers in Chicago, alone, number over 50,000. He has established a bank, a printing house, a land company, a lace industry, and a new town of Zion, at Waukegan, Wis., containing 6500 acres. His members pay a tithe of all their earnings to the church, and his financial resources are placed at two million dollars. During last month he started on a pilgrimage to the Holy Land, having made a vow that he would witness the sun rise over the hills of Jerusalem, at the dawn of the twentieth century.

One other divine healer so-called, however demands attention, namely Mrs. Mary Baker G. Eddy, the discoverer of Eddyism, or Christian Science, the most popular fad and delusion of the day. Some idea of the extent of this delusion may be gathered from statements made in the Christian Science Journal for December last, in which it is claimed that there are 370 Christian Science churches, and 100 other organizations in existence; in addition there are 100 reading rooms, and 30 institutes and academies where Christian Science is taught; several magazines are published, and churches are found in nearly every State in the Union, and in Canada, England, France, Germany, Australia, and Hawaii. Boston and Chicago are the great strongholds. In the former city the Mother Church has been erected at a cost of over $200,000.

It is claimed that 1,000,000 persons have received Christian Science treatment, and that the number of believers is over 400,000 in the United States alone. So much for the extent of the fad. Now a few words as to the founder or "discoverer," and its claims and practice. The "discoverer," Mrs. Mary Moss Baker Glover Pattison Eddy, the last three being the names of her successive husbands, is an old woman of 80, living at Concord, N. H., where she has a stately mansion, and another at Boston, Mass. She descends from an old New England family, and in childhood was fond of metaphysical studies, logic, etc. Like Schlatter, in her childhood, she heard voices calling her by name—"three times in an ascending scale," this continued for a year.

She was a member of the Congregational Church, an ardent advocate of woman's rights, and a practitioner of homeopathy. Like the Rev. John Alexander Dowie, her introduction to the new system was brought about by her recovery from a supposed serious illness, following a fall upon the ice; her physician had announced that there was no hope for her recovery, that she could not possibly live three days. Like Dowie, she then resorted to prayer and the Bible; opening the book she read of the palsied hand; she was immediately restored to health, arose from her bed, and appeared to her friends as one arisen from the dead. This was in the year 1886.

She then began a close study of the Scriptures, and at the end of three years published her book, "Science and Health, with Key to the Scriptures," which has had a marvelous sale, having gone through over one hundred and ninety editions, and is carefully protected by a copyright. This marvellous book, which has been spoken of by enthusiastic converts as "a rich word from our leader and teacher, our beloved Mother in Israel." (Galton.) That "tears away the veil which more or less has darkened the pages of Scripture and, endues them with the brightness which God's words should reflect." (Clarkson.) A book so sacred, that in their church service selections are read from the Bible and from the book alternately; further I am informed, that in the magnificent Mother Church in Boston there are two windows, in one of which is a figure of our Lord, and in the other a

representation of "a woman clothed with the sun, and the moon under her feet, and upon her head a crown of stars."—Rev. xii: 1. This woman, Christian Scientists claim, is Mrs. Eddy, and her book is the book mentioned in Revelation. Still further, around the walls of the church are quotations signed alternately, "Jesus Christ," and "Mary Eddy," who is spoken of as "Our Mother." And, yet, Mrs. Eddy deemed it necessary to cover this book by a copyright, and to make it a patented article, on the same plane with Lydia Pinkham's Vegetable Compound, or Radway's Ready Relief.

And she has been called by her devotees, "the most illustrious woman of the Continent," "The most marvellous woman of the ages, a second great Mary, who has taught the world how to know God."

But sacrilegious, aye, blasphemous as all this is, it is not with Christian science as a religion that we are most concerned, but with Christian science as a medical delusion, as a pretense to healing.

Septimus J. Hanna, editor of the *Christian Science Sentinel*, says: "Christian scientists rely upon God and divine power for their healing in every way, and every emergency rather than upon human physicians." In other words, Christian science pretends to treat every kind of human ill without resort to medical means—claims to cure cancer, consumption, diphtheria, scarlet fever, all other fevers, and all inflammatory diseases. A consistent application of this belief would apply to fractures, dislocations, bleeding arteries, and other injuries, but Mrs. Eddy says: "It is better to leave the adjustment of broken bones and dislocations to the fingers of the surgeon, until the advancing age admits the efficiency and supremacy of mind," thereby showing her cunning, for sufferers from such injuries live to bring the scientists into courts, as defendants in suits for malpractice, "but dead men tell no tales." The theory underlying this treatment is a species of pantheism in which the reasoning is something like this: God is good; good is Mind: God, mind being all, matter is nothing.

Sin, sickness and death cannot affect God, therefore they cannot affect Mind, which is God. There are two forms of mind—Divine Mind and Mortal Mind. Mortal mind is responsible for all the trouble in the world, especially for sin, sickness and death; mortal mind is also responsible for a belief in matter. "Matter is a subjective state of mortal mind evolved in belief by false, material sense." But mortal mind being a subjective state it really has no existence and disappears with the development of a firm belief in Divine mind; as mortal mind disappears, with it also goes the belief in matter or material things, and sin, sickness and death. This being the theory, how is it applied? The Christian science healer sits beside the patient, who is suffering from the delusions of mortal mind, and thinks he is sick, and endeavors to argue the false impression away; allays his fears, positively assures him that there is no disease or suffering, and endeavors to replace his false beliefs by a belief in Divine mind; this is helped by prayer and reading from Mrs. Eddy's book.

A word with reference to Osteopathy. Like Christian science, this system announces to treat all diseases without the use of medicine—like Christian science it accounts for all diseases by a fanciful pathology: Christian science teaches that all diseases are due to errors of mortal mind. Osteopathy, "that bodily disorders are the result of mechanical obstruction to the free circulation of vital fluids and forces." "What is pneumonia? It is a congestion; it is too much blood in the lungs. What is typhoid fever? It is too much blood in the small intestines. What is diphtheria? It is too much blood in the membranes of the throat. What will cure these troubles? Correct the circulation; make the circulation absolutely perfect, and these so-called diseases will at once depart."

Like Christian science, osteopathy discards the germ theory of infectious diseases, throws aside all the discoveries of bacteriology, ignores all the results of the investigations of the great army of patient, honest students the world over; and substitutes in their place simply—manipulation. Like Christian science its backs up its claims to recognition by great numbers of patients, and names of persons noted for intelligence and influence.

I will not weary you by further citations to establish the propositions made above. I think you will agree with me that their demonstrations are complete. Do the present prominent medical delusions, Christian science and osteopathy, point to their great following, and claim among their followers persons of prominence and intelligence? Let me refer to the above statements, and remind you that Francis Schlatter and Dowie can claim the same, or that further back Cagliostro and Perkins were accorded a like support. Osteopathy may claim its thousands, and Christian science its tens of thousands, but Lydia Pinkham numbers her patients at a million.

But, now I hear you ask, why is this? Why can humanity be thus befooled? There are several reasons to be offered.

First: The self-limitation of diseases. A large percentage of all the ailments affecting humanity, some say over fifty per cent., for which medical aid is sought, tend naturally to get well, and will get well under good care and proper hygienic influences, without any special medical treatment. This is self-evident to the profession, but not to the laity. With the people, sickness is a calamity that always requires some special medical means to remove, and added to this mistaken belief is a false method of reasoning, or accounting for recovery—namely that recovery is always attributed to the means used, in other words a sequence is taken for a consequence; a *post hoc* for a *propter hoc*.

Again a large number of ailments that are very serious in their character to the patients are simply functional troubles, due largely to our unnatural way of living. Consider the overtaught, underfed or improperly fed and villainously dressed children; overworked, overstimulated men; and women who violate every canon of health as to rest, recreation, food, clothing and general living; add to this the noise and confusion of town life, the daily rush and rapid way of doing everything—the constant jingle, jingle, jingle of the telephone bells and street cars, the clack, clack of horses' feet on paved streets, the clanging of church bells and the roar of steam whistles, and do you wonder that the harvest of such sowing should be unbalanced nervous systems—the so-called nervous prostration, hysteria, neuralgia, dyspepsia and melancholia?

In the management of all these ills, the personal factor of the medical adviser is a powerful one. Pettigrew says: "The bold unblushing assertion of the empiric of a never failing remedy, constantly reiterated, inspires confidence in the invalid, and not infrequently tends by its operation on the mind to assist in the eradication of the disorder." But not only in self-limited diseases and neurasthenia is the personal factor of the medical adviser of great importance. In all kinds of sickness and in every physical calamity this personality is, and ought to be, a powerful agent in affecting relief; and it behooves the educated physician to avail himself of this agent in his combat with disease.

Much is now being said of suggestion as a therapeutic agent. As defined by the Century Dictionary: "Suggestion is the insinuation of a belief, or impulse into the mind of the subject by any means or by words, or gestures, usually by emphatic declaration." A late writer says: "The presence of the physician who inspires his patient with confidence and hope is a constant suggestion that health will be restored." How often do we hear the patient say, "I was better the moment the doctor came into the room." The tactful physician says to his bed-ridden, neurasthenic patient, "I shall expect to see you sitting up to-morrow when I come." And the patient will, in all probability, be sitting up. The next day he will say, "I shall be greatly disappointed if you do not meet me down stairs to-morrow," and in all probability he will be met as he suggested. No finer example of the magical influence of the doctor's presence was ever given than that described by MacLaren, when Burnbrae's boy had his hand mangled by the threshing machine and they were waiting for Dr. MacLure to come. It was often told how far he was up Glen Urtach when the feeders of the threshing mill caught young Burnbrae, and how he had only stopped to change horses at his house and galloped all the way to Burnbrae and flung himself off his horse and amputated the arm and saved the lad's life. "You wud hae thocht that every meenut was an hour," said Jamie Soutar, who had been at the threshing, "an' a'll never forget the puir lad lying as white as death on the floor of the loft wi' his head on a sheaf, an' Burnbrae haudin' the bandage ticht an' prayin' a' the while, and the mither crying in the corner. 'Will he never come?' she cries, an' a' heard the soond o' the horse's feet on the road a mile awa' in the frosty air. 'The Lord be praised!' said Burnbrae, and a' slippit doon the ladder as the doctor came skelpin' intae the close, the foam fleein' fae his horse's mooth. It was michty tae see him come intae the yaird that day, neeburs; the verra look o' him wes victory."

But admitting as we do that a large percentage of ailments do get well without active medical interference, fifty per cent. if you will, also that a considerable number are conducted safely to health by the personal influence of the physician, by suggestion, or whatever you like; there remain still a large number of diseases in which the powers of nature and the forces of disease are engaged in a death grapple, that will result disastrously to the victim unless nature have the most prompt and most efficient aid—aid that can be given, and be given only by the educated, scientific medical man. Of the great number of such diseases time will permit me to refer to but two or three.

Dr. Nicholas Senn, at the last meeting of the American Medical Association, in a discussion of appendicitis, admitted that eighty per cent. of all such attacks get well without operation. This is a very generous admission for a surgeon, but grant it, what is to become of the other twenty per cent.? What can manipulation, or faith, or Christian science do for a perforated, suppurating gangrenous appendix? Modern surgery claims to cure ninety-eight, or even a hundred per cent. of such cases, if the operation be done early, and the claim is well founded. Grant, also, that eighty per cent. of pregnant women approaching delivery will get along safely without any special medical aid, but what of the other twenty per cent. of cases in which there is very likely to be puerperal convulsions, or hemorrhages, or malpositions, cross presentations, in which if the patients do not have the care of the best medical skill they will in all probability die; but with such skill they will almost invariably recover. And diphtheria, that most terrible enemy to child-life, that has planted the yew and cypress in every graveyard of the land; that has made more hearthstones lonesome, and more hearts sad than any other malady; that has caused lamentations and mourning throughout the world—Rachels weeping for their children and refusing to be comforted because they are not.

The efforts of the best men in the profession were as nothing—with fiend-like rapacity this modern Moloch claimed the best and dearest of our homes, and the insatiate monster still cried for more. But thanks to modern medical science, thanks to the germ theory of disease, the deliverer has come, and this fearful scourge has been

robbed of its terrors, for antitoxin cures diphtheria. Modern medicine says: "Go tell every fond mother and every devoted father that antitoxin properly administered and in time will cure diphtheria." This is my confession of faith, that the proper dose of antitoxin administered during the first twenty-four hours and repeated as necessary, gives promise to cure every case of diphtheria, and if given during the second twenty-four hours, will cure ninety per cent. of such cases; and this is the faith of my profession!

And yet Christian science and osteopathy have the brazen effrontery to assert that they treat all diseases without calling "upon the human physician," and "without the use of medicine," and by circulars and advertisements in the papers make these statements to a confiding and easily deluded public. Any man, or any set of men, who depend upon manipulation, or upon prayers in cases of appendicitis, or who undertake to conduct pregnant women through the perils of maternity by the same means, or who withhold from children the almost miraculous benefits of antitoxin in diphtheria, and who by their "bold and unblushing assertions" publicly reiterated, mislead and delude the people, are dangerous men, a peril to the community and ought to be suppressed.

But what of the future? History will but repeat itself; the royal touch for king's evil, Perkinism, Mesmerism, Thomsonianism, Schlatterism have all gone, to be remembered only as historical curiosities, and to illustrate how far humanity may be fooled. Only a few years ago our ears were filled with the adulations of Keely and his institutes, and good men with the dollars, and pious women with their prayers were doing their best to convince the world that the great deliverance to the drunkard had come. But the glory of Keely has departed, and his was another light that failed. So will it be with Dowicism, and Stillism, and Eddyism, they are little clouds, they will soon pass, and the names of Dowie, and Still, and Eddy will take their places by the side of Mesmer, and Perkins, and Thomson, and Schlatter, and Keely, who lived and flourished for a time, and then died.

But what can be done? Should anything be done to combat these false leaders of the people? Purrington says of Christian science: "Publicity will destroy this cult far more quickly than legislation." Many States of the Union have passed laws regulating the practice of medicine, but the term "practice of medicine" has been so imperfectly defined by the courts that these laws offer little, or no protection to the public. "The use of drugs, medicines or instruments" in treating the sick or injured, the definition usually given by the courts, would convict a druggist who prescribes a dose of chalk mixture for diarrhea, and would permit an osteopath or a Christian scientist to escape, who allows a child to die of diphtheria without antitoxin, or a woman in labor to die with her child undelivered. The "glorious uncertainties of the law" are well illustrated by the fact that the State of Kentucky excludes the osteopath absolutely, while the neighboring State, Ohio, can find no justification for this exclusion.

From all that has thus far developed it seems conclusive that with the present definition of the term "practice of medicine" that attempts to execute the laws now existing would simply give the pretender a little cheap martyrdom, and aid rather than deter him in his nefarious business.

It behooves all practitioners who have complied with the medical registration laws to unite in an appeal to the legislature for the passage of an act defining justly the term "practice of medicine," so as to include "all methods of treating the sick and wounded for hire," or, as stated most intelligently by Mr. John A. Opp of the Luzerne County bar, in an opinion as examiner to report upon the application for a charter by the new school of osteopathy, in this city. In this opinion which was adverse to the application, Mr. Opp says:

"We conclude, therefore, that a medical practitioner is one whose business, or profession, is to heal diseases, whether it be by drugs, medicine, electricity, hot or cold water, or massage. That the practice of medicine as used by the act of 1877, is the attempt to cure any person, sick or afflicted, by the use of medicine, or by any means or agency whatsoever; that the word 'medicine' in such statutes is used in its broadest sense and means any curative agency." Such a definition would make it necessary for all persons pretending to heal to come before the State Board of Medical Examiners and to meet the same requirements as are demanded of legal practitioners.

Medical legislation has been productive of much good—it has produced a higher standard of medical education; it has closed the diploma selling mills; it has placed the profession on a higher plane, and enabled it to command a much greater respect in this age of the world; and it has aided in making the profession more and more powerful to combat disease. Without doubt, the present medical delusions will pass, as all their predecessors have passed, but they will be succeeded by others, as the genus has always existed—false lights along the shore to mislead the unwary, to shipwreck and ruin; but the great sun of true medical science will continue to shine with greater and greater effulgence until the perfect day.

Finally, may we not indulge ourselves in the poet's rhyme:

"Swift pass the days. Our century slowly dies—
Quick beats her pulse and filmy are her eyes.
Her flowing robes are red with countless wars,
Her tender breasts are sad with many scars;
Yet in her dying eyes prophetic glows
Some sweet prediction of a world's repose.
Lo, at her side the coming sister stands,
And bends to hear, and fold those wasted hands.
What shall I bring which thou hast failed to find?
What nobler hope have I to give mankind?
Hark! From the lips where life had seemed to cease
Comes the low murmur: "Thou shalt give them Peace."

SOME STUDIES IN METABOLISM IN CHRONIC NUTRITIONAL DISEASE.[1]

By G. W. McCASKEY, A.M., M.D.,
OF FORT WAYNE, IND.;

PROFESSOR OF CLINICAL MEDICINE AND NERVOUS DISEASES IN THE FORT WAYNE COLLEGE OF MEDICINE; PRESIDENT OF THE INDIANA STATE MEDICAL SOCIETY.

It cannot be emphasized too strongly in the practical study of the phenomena of health and disease that, as far as the limitations of our knowledge enable us to determine, vital phenomena of every sort are reducible to chemical formulæ. Look where we will, or analyze as far as we can, we will find ourselves unable to go beyond this proposition. The microscope has told us much and revealed wonders in the minute structural formation of organized bodies; but in spite of all this it leaves us absolutely in the dark as to the real nature of the processes which in some sense are equivalent to the life phenomena with the study of which we are especially concerned. It therefore becomes necessary, after pursuing our investigations as far as we can with the microscope, to lay it aside and pursue the further elucidation of the problems of life with the test-tube and balance in the chemical laboratory.

When we attempt to make a practical application of these obvious truths in the study of vital processes we are at once confronted by a painful sense of the imperfection and sharp limitations of our knowledge. We see at once that we know but little more than the alphabet of the wonderful array of complex chemical processes which go to make up the phenomena of the cellular and somatic life represented by the higher animal organism. But this alphabet is already a pretty large one, and its complete mastery and application to clinical methods will do as much if not more toward furnishing a clear and lucid comprehension of diseased processes than anything else with which I am acquainted.

As illustrative of the high value attached to investigations along these lines I desire to present a few facts gleaned from the daily grind of routine clinical work.

In looking for a convenient accessible and faithful reflex of the chemical processes going on within the body which we designate by the blanket term "metabolism," the urine presents itself as *par excellence* the material best suited for our purpose. The obviousness of this proposition makes comment unnecessary further than to point out the fact that practically everything existing in the urine is preformed in the blood; has served its purpose in the economy, and is carried away by the currents of renal secretion as effete material. The kidneys are not in any proper sense of the word secretory organs, as they are entirely destitute, as far as we know, of proper secreting glands, their exclusive function being to act as separators, to speak, of certain materials held in solution in the blood which it is to the advantage of the economy to throw away. The theory that uric acid and certain other urinary constituents are formed in the kidneys has been entirely disposed of by the investigations of Minkowski and others, and we are fully justified from a practical point of view in regarding every molecule which is found in the urine as identical with one which preexisted in the blood, at the same time admitting certain unimportant modifications produced by the renal epithelium, such as the synthesis of hippuric acid, from benzoic acid and glycocol in Munk's experiment.

In singling out the urine for the purpose of clinical study in the manner indicated, it is not my intention to underestimate the importance of pulmonary, cutaneous, or intestinal excretion. The technical difficulties, however, in the way of the chemical investigation of these latter excretory products, together with the fact that the chemical combinations found in the intestines are mostly of local origin, make them unavailable as standards for clinical study.

Turning to the urine and seeking for evidences as to the state of general metabolism, the greatest interest centers in the end-products of nitrogenous waste. Of this, urea is by far the most important; next in order comes uric acid, and after this the xanthin bases. The adequacy of the chemical processes of the body in the genesis of the life forces is indicated by the total quantity of urea per unit of body weight better than by any other, if not all other, facts combined.

In the study of chronic nutritional disease of various sorts, they can be divided, it appears to me, to advantage in three groups; one with diminished urea excretion; another with excessive, and a third with normal, or, as I think they might be conveniently designated, hypoazoturia, hyperazoturia, and orthoazoturia.

As an illustration of the first group I have recently selected from my notes forty cases of neurasthenia with marked hypoazoturia, the average of the entire forty cases being less than 10 grams, or about 155 grains per day. The lowest quantity found was 2 grams in one case and 3.25 in another; ten cases had 5 to 6 grams and the remainder ranged from 6 to 19. In such cases important therapeutic indications are obvious and, with perhaps the single exception of renal insufficiency from organic disease, forced feeding is indicated, in many cases, with hydrotherapeutic or other mechanical measures, and outdoor life, to stimulate as actively as possible the various functional and nutritional processes.

In the second class of cases (hyperazoturia) we find numerous chronic morbid states among which diabetes mellitus occupies a conspicuous position, in which tissue metabolism is excessive and the output of urea greatly in excess of what it ought to be. For instance, in a recent case of diabetes in a young girl weighing 95 pounds, the quantity of urea was 48 grams, or about one and one-half ounces, for an adult weighing 150 pounds. It is not, of course, always possible for

[1] Read before the Indiana State Medical Society, May 24, 1900.

us to meet the therapeutic indications arising from such a condition, but the salient fact of excessive metabolism is an important one and should be taken into close account in dealing with this group of cases.

In the third, small group of cases (or those of orthoazoturia) we find the urea excretion strictly within the normal range, and yet have to deal with obvious chronic morbid nutritional states. Where a proper balance is maintained in the intake and output of nitrogenous material and yet severe nutritional disturbance presents itself, we will commonly have to deal with toxic conditions resulting from functional disturbances of some one or more of the principal organs of the body. This may not be true in the first and second groups. In studying the urea excretion, care should be taken not to lay too much emphasis on the results of a single analysis, as the amount is subject to tremendous fluctuations from various causes, transient and even unimportant in their bearing on the pathology of any given case. A series of analyses of measured twenty-four-hour collections is advisable in all cases were unusual conditions are met with.

Taking up the question of uric acid as the next most important product of nitrogenous waste, we find it subject to wide fluctuations from many different causes, some of which are reasonably plain and others entirely obscure. It seems to be pretty fully agreed that uric acid is derived from the nuclein substances of the organism; and that the latest investigations of Horbaczewski indicate if they do not prove that it is derived directly from these substances and not from the xanthin bases as intermediate oxidation products. The chemical formulæ of uric acid and the different xanthin bodies placed side by side with their gradually descending molecules of oxygen, furnish a very picturesque argument in favor of each of these bodies being derived from the next lowest oxidation product. This theory appears to be quite untenable.

With reference to the prevailing view that uric acid is derived principally from the nuclein of the white blood-cells, I have to oppose some clinical observations which I cannot explain in accordance with this theory. For instance, in one case of splenic myelogenous leukemia, my study of which has extended over a long period, the quantity of uric acid in 24 hours has fluctuated widely, being as low as 1 gram and as high as 2 1/3 grams (15½ to 36 grains); the leucocytosis in this case has varied from as low as 10,000 up to 277,000 per cmm., the leucocytes being thus at one time 27 times as numerous as at another. I have been unable at any time to trace a correspondence between the number of the leucocytes and the amount of uric acid excreted. For instance, at one time with the leucocytes at 10,000 there was 1.1 grams of uric acid while at another with the white-cell count up to 277,000 the uric acid was 1.6 grams; with another white-cell count of 11,000 the quantity of uric acid was still above one gram, and yet again with a count of 20,000 there was 2.7 grams of uric acid. Obviously there was no connection in this case between the number of leucocytes and the quantity of uric acid excreted. In another case of fatal heart disease, under the care of Dr. Campbell of Ada, O., there was a very marked leucopenia, the white cells being found only to the number of 1300 per cmm.; and yet two different estimations of uric acid showed respectively 1.59 grams and one gram, both amounts being considerably above what is regarded as the physiological standard. If time permitted I could quote numerous cases along these lines, showing an utter lack of correspondence between an increase and decrease of leucocytes and uric acid.

What was said with reference to the relation of the xanthin bases to uric acid is probably also true with reference to the relation of uric acid to urea. The most we can say in the present state of our knowledge is that variations in the amount of uric acid simply indicate perturbation of normal metabolic processes which always have a more or less important bearing upon chronic nutritional disorders. The largest quantity of uric acid that I have ever found and, so far as I know, larger than has been found in any recorded case, was in the case of diabetes already referred to, in which the Hopkins method showed 90 grains in twenty-four hours. Three different titrations were made, each one giving approximately the same result.

I use a modification of the Hopkins method in my laboratory, the correctness of which I have verified many times by making percentage solutions of uric acid and making control titrations with them. With reference to uric acid in diabetes, I notice that Startz of Germany is said to have pointed out some sources of error, the exact nature of which I do not know as I have not yet had an opportunity of consulting the original monograph.

There are many other important indications to be found in the urine bearing on the processes of general metabolism. I might mention in this connection the occurrence of leucin and tyrosin as indicating a perversion of nitrogenous metabolism commonly associated with acute atrophy of the liver, but also found in numerous and varied chronic nutritional disorders, among which I may mention, as having occurred under my own observation, Brights' disease, leukemia and chronic hepatic congestion and chronic gastro-enteritis. The occurrence of these bodies is not pathognomonic of any particular disease, but simply indicates changes in the chemical processes of the tissues, the precise meaning and character of which are still obscure.

Variations in the quantity of the various inorganic salts present problems of great interest which I cannot now consider. In this connection the sulphates are perhaps of the least importance, variations in their amount being principally due to dietetic influences. There is good reason for believing, however, that this is not true with reference to the phosphates and chlo-

rides, variations in the quantity of which have more or less direct significance with reference to the metabolic processes of the organism.

It has been my intention simply to point out a few interesting facts which have fallen under my own observation and indicate what appears to me to be their bearing upon the practical problems of clinical medicine. In this direction there lies one of the most fertile fields for original clinical observation, the cultivation of which will broaden our views of disease processes and furnish us many an important hint in the management of obscure pathological conditions with which we have heretofore dealt under great difficulties.

THE ART OF KEEPING COOL. WITH SPECIAL REFERENCE TO THE PROPER USE OF WATER.

By RALPH WAIT PARSONS, M.D.,
OF SING SING, N. Y.;
ASSOCIATE PHYSICIAN, GREENMONT-ON-THE-HUDSON, SING SING, N. Y.

The object of this communication is to show, as briefly as may be, how, by the judicious use of water both internally and externally, we can keep ourselves comparatively comfortable during the warm weather and can avoid suffering to a considerable extent from the ill effects produced by a prolonged season of summer heat.

A great many persons either do not know how to properly use or have a prejudice against the use of cold water, and to such it behooves us to show the advantages, and to point out a few practical results which may be obtained by the correct use of water which will tend to add greatly to their physical comfort.

Internal Use of Water.—Cold water taken in moderate quantities and at frequent intervals during the day not only acts as a flush to the stomach and intestines, but tends to improve the appetite, increase peristalsis and relieve constipation. It also stimulates the liver, heart, kidneys and skin to a healthy action. Its effects on the kidneys are not only to increase the watery, but also the solid constituents of the urine. As tissue metamorphosis is greatly enhanced by water, the organism will be much rejuvenated by its moderate and systematic use. By introducing water in small and frequent quantities, either into the stomach or rectum, we can obtain a reduction in the bodily temperature, which is due not only to the direct effects of the cooling properties of the water, but to reflex action. It also has a tendency to lower the temperature of the body directly by means of stimulating the function of the sweat glands.

The skin is not only an organ of sensation, but it has also the function of (*a*) secreting the sweat, (*b*) a respiratory function, and (*c*) an excretory function. The amount of insensible transpiration given off from the skin has been estimated to be on the average about 900 grams per day. The amount of sensible perspiration, or sweat, varies very greatly in amount in accordance with the height of the temperature, the amount of muscular exercise, the quantities of fluids imbibed, and other factors. The skin has a distinctly respiratory property. It has been estimated by Aubert that the amount of carbonic acid given off by the skin in the course of twenty-four hours amounts to 198 cc. while the body is in a state of repose. The skin, in addition to excreting carbonic acid and sweat, also excretes, by means of the sweat, an organic substance similar to albumin, of which there are however but traces, and a free volatile acid which gives to the sweat its acid reaction and odor.

In this place it may be of interest to recall the composition of the sweat, which is as follows:

Water	995.50
Sodium chloride	2.23
Potassium chloride	0.24
Sodium and potassium sulphates	0.01
Salts of organic acids	2.02
	1000.00

It follows from the above considerations that the normal functionating of the skin is essential to good health and to a personal sense of well-being. The proper action of the skin may be impaired by ill-health, various diseases of the skin, nervous disorders, etc.

It may be of interest to note here that in some person the sweat, either owing to the nature of the free volatile acid or organic matter, or both, has a very disagreeable and even offensive odor. In addition to keeping the skin in a proper cleanly condition by means of frequent ablutions, the use of some alkaline mineral water, or for convenience, one or two three-grain effervescent tablets of citrate of lithia, will be found of service. The tablets should be taken three times a day in a glass of water. Ice water should be prohibited. The water, if desired, can be sufficiently cooled, by being placed in bottles in a refrigerator.

External Use of Water.—Some of the most important and beneficial effects of water are obtained from its external use. Not only does it have a cleansing, antiseptic and stimulating action on the skin, but also a stimulating effect on the circulatory, respiratory and nervous systems. Tissue metamorphosis is also stimulated by the external use of water, as well as by its internal use. Water at the same time has the property of absorbing heat, and when applied to the surface of the body will abstract heat therefrom, the amount of heat thus abstracted varying according to the temperature of the water and to the length of the application. The effect of the application of cold water to the skin for a short time causes increased blood-pressure, strengthens the heart's action, stimulates the pulmonary circulation, and causes a tonic contraction of the capillaries. All these effects tend to hasten the blood-flow, and as it circulates more rapidly in the skin than usual, it tends to give off heat more

readily. These effects are still further enhanced by the mechanical action of water on the skin when directed from a height or from a distance. The value of the mechanical effects of water have been fully recognized, especially in the last few years, and the use of water under pressure in public baths in many State institutions, and even in small private hospitals, is an evidence of the high therapeutic estimation in which it is held.

Bathing in Warm Weather.—Having considered in general terms the effects produced by cold water when applied to the skin for a short time, let us see what benefit and comfort can be derived from the use of cold water or of warm water, followed by the use of cold water. On rising from bed in warm, and especially in sultry weather, one feels as a rule a sense of lassitude, and in general there is a lack of nervous tone. The skin is relaxed and may feel moist and clammy. A lack of refreshment is felt, although sleep may have been sound, and an indisposition to take up the business cares of the day. This is the time for the cold bath. The bather should immediately on rising take a dip in water at a temperature ranging from 60° to 70° F., the bath lasting from one-half to one minute and to be followed by a vigorous rub with a coarse bath-towel. It is still better, in order to obtain the mechanical effects of the water, to have a couple of pails of water at the above temperature dashed over the bather from a distance. If one has a shower bath it is equally good. If the bather is not accustomed to such baths, or is not very robust, he should begin by taking the baths at a little higher temperature, and then gradually accustom himself to the temperature of 60° F. If the friction with the towel can be done by another person, so much the better.

The result of taking such a bath as this is very manifest. It is a powerful stimulant to the heart and nervous system and inaugurates a sense of well-being which had not existed before the bath. The skin takes on a healthy glow, the appetite is improved, and, in short, the whole organism is rejuvenated, and the individual is enabled to undertake his day's work with energy, and to resist much better the depressing effects of the warm and sultry season of the year.

At the close of a hot day in summer there is nearly always a feeling of more or less nervous exhaustion, and on retiring, owing to the heat and fatigue, sleep is delayed, and frequently when it does come is fitful and restless in character. At such a time the bath is a great boon. The bath proves more efficacious, I believe, when taken at a temperature of from 103° to 105° F., lasting for from three to seven minutes. The warm water not only cleanses the skin, but is mildly stimulating and causes only a moderate congestion. At the end of from three to seven minutes cold water at the temperature and as before mentioned should be used. A marked reaction ensues, together with its accompanying stimulating effects, and after a brisk rub the bather can go to rest and in the large majority of cases enjoy a good night's sleep, although the temperature is very high.

For women and children it may be preferable to begin the use of the baths with a less marked difference between the temperature of the warm and cold bath. Thus, a bath at 103° F. followed by a rain or shower-bath at 85° F. might be given. What is steadily aimed at is the securing of a good reaction with its attending beneficial results. After a time the difference between the temperatures of the water can be gradually increased with good effect. It may be desirable, also to rub the body gently with the hands, in order to still further stimulate the flow of blood through the skin.

The use of the baths as described should be made a matter of habit, in order that they may be taken regularly and systematically, thus securing the good results indicated. The improvement in the general health and the ability of the organism to better withstand the exhausting effects of warm weather will soon be manifest. In case, however, of the existence of disease of the skin, or of some serious affection of the heart or lungs, the physician would, of course, give such special directions as might be required.

It is only necessary to touch upon the fact here that a large proportion of the inhabitants of our large cities can seldom indulge in the luxury of a bath. In many of the European cities public baths are provided for the people; and in this country a few cities have adopted them. But it is only within the last few years that a cleanly system of public baths has been provided for the poor in New York City. So far these baths are very inadequate to meet the demand, and it is hoped that a sufficient number of bathing places will be placed in the thickly populated districts of New York in order to meet the public requirements as well as to fulfil the needs of public health and cleanliness.

As supplemental to the beneficial effects of the uses of water, the importance of paying close attention to the digestion and regulation of the bowels should not be overlooked. The diet should be moderate in quantity, plain and non-stimulating, consisting largely of fruits and fresh vegetables. Abstinence from alcoholic beverages, especially during the summer months, should be strongly insisted on. Alcohol tends to lower the vital powers and has a depressing effect on the brain and nervous system, rendering the individual much less capable of resisting the ill-effects of hot weather, especially the condition known as heat prostration, or sunstroke.

The clothing should be light and loose. The underclothes may be light woolen, or cotton and wool, the principal point being that the garment should be porous in texture.

Avoidance of drafts is recommended, although it may be said in this connection that the tendency to "catch cold" or to get a "stiff neck" when unavoidably exposed to a draft will be much diminished, if the methods of bathing

herein suggested are faithfully carried out. The skin will have become toughened, as it were, by the use of cold water, and less sensitive to drafts and sudden atmospheric changes.

THE DOSE OF POTASSIUM IODIDE. WITH REFERENCE TO ITS UNTOWARD EFFECTS UPON THE UPPER RESPIRATORY TRACT.

By LEWIS S. SOMERS, M.D.,
of Philadelphia, Pa.

There are four groups of affections of the upper respiratory tract in which potassium iodide, to a greater or less extent, is indicated either to relieve symptoms, to restore the integrity of the parts, or as an aid in diagnosis.

The first group embraces the new formative and destructive lesions of syphilis: that is, the phenomena so frequently observed of tertiary syphilis of this region. The second in point of frequency consists of non-specific changes of the mucosa, characterized by deficient secretion and an abnormal degree of dryness, the drug being used to increase glandular secretion and thereby relieve the nasal or pharyngeal distress. The third group, in which it is used more or less frequently as an aid to diagnosis, is one requiring careful study in the individual case and is sometimes of great value in the diagnosis of new formations of the pharynx and larynx from obscure syphilitic growths, or to differentiate in conjunction with other measures a carcinoma, for instance, from a gumma of the tonsil. In some of these cases the utmost difficulty may be encountered in accurately recognizing the condition present and the well-known effect of this drug in certain syphilitic states, the disappearance of a gumma following its administration and the opposite in malignant growths indicate its use for this purpose. This latter statement needs qualification to a certain extent, however, for in malignant growths and even tuberculous tumors of this region favorable symptoms are sometimes seen for a few weeks after the potassium iodide has been used. A short period of observation, bearing this in mind, however, will enable one to see into the nature of the affection and the influence exerted on it. Finally, the drug is of value in certain specific granulomata, as actinomycosis, which on account of their rarity require no further mention.

It is not desired to especially indicate the use of potassium iodide in the affections enumerated, but to call attention to the phenomena of iodism of this region and the peculiar susceptibility in some cases and tolerance in others to minute and massive doses. "A curious phenomenon is the production of iodism from small doses and, in contrast, the comparative immunity which attends the administration of large quantities."[1] The following cases show this in a marked manner, the first being one of unusual susceptibility.

Mrs. L., aged twenty-two years. She was seen September 22, 1894, complaining of excessive mucous discharge from the nasopharynx and frontal headache, following typhoid fever (?) three years previous. The nasal arch was flattened and from certain objective symptoms and her mode of living, tertiary syphilis was strongly suspected, although no direct history of infection could be obtained. She was placed on ten grains of potassium iodide, three times daily, and within twenty-four hours all her mucous membranes were secreting in excessive amounts, the upper respiratory tract and the mucosa of the eye and ear were inflamed, as was also that of the intestinal tract, vomiting and diarrhea being constant. There was headache, but not any dermal eruption and the symptoms of which she previously complained were intensified. These symptoms attained their maximum in twenty-four hours after the first dose, which was the only one taken, and continued in a violent form for three days, gradually declining and entirely disappearing in three weeks. Two weeks after complete recovery from the attack produced by ten grains she was given, without her knowledge, one grain of the drug and all the symptoms noted made their appearance within a few hours and continued for three days. One grain of potassium iodide in this woman, therefore, produced exaggerated symptoms of iodism.

The case by contrast which was seen in December, 1899, was that of J. S., male, aged forty years, who had been advised by a friend to take potassium iodide for an attack of rheumatism. There were no indications of syphilis and he denied any history of such. He had the drug put in powders each containing 240 grains; one of which he took in a glass of beer after each meal. When I first saw him on December 27th he had taken the drug for three days in the dose mentioned—a total of 2160 grains—and had practically no symptoms. There was some nasal congestion and a subacute conjunctivitis, but nothing more at the time and nothing further developed.

In a somewhat extended search of the literature I am unable to find a duplicate of the second case, especially bearing on the massive dose taken in such a short time with practically no symptoms, but numerous cases have been reported in which, commencing with a moderate dose, the patient has ultimately attained large amounts without symptoms of iodism. Cases similar to the former, however, are comparatively frequent when somewhat larger amounts of the drug were administered, such cases having been reported by Bringier,[2] F. P. Brunthaver,[3] Montgomery,[4] and others.

The question then naturally arises as to the value of potassium iodide used to determine, in relation to its reaction, the presence or absence of specific infection. It can no longer be considered that the tolerance to large doses indicates the presence of syphilis, as the cases in which it may be used and in which syphilis can be eliminated are of frequent occurrence, too frequent

to prove by being exceptions the older idea in this respect. Peculiar, however, is the fact that in a number of individuals, both with and without tertiary syphilis of the upper respiratory tract, minute doses are ofttimes followed by iodism, while in some if the drug is pushed these untoward signs will subside and not again appear. In another class large initial doses will be of value and no iodism will take place. I have observed cases of tertiary lesions, in which the nasal interior was destroyed, including the vomer and portions of the palate bones, in which five grains of the drug would produce iodic symptoms of sufficient intensity to compel its discontinuance, although after these untoward symptoms had disappeared thirty to fifty grains were given at a dose, with the most favorable results and with the entire absence of iodic phenomena.

The size of the dose, therefore, should be measured by the effect produced on the disease or symptoms for which it is given, usually moderate doses of from five to ten grains three times daily are sufficient, and while improvement for a time will be observed in certain cases the good results will only become apparent when the amount administered is increased. On account of this peculiar relation to the drug, the dose makes little or no difference in its effect as regards iodism and in some instances, should congestion of the upper respiratory tract be developed after the administration of small initial doses, the symptoms will disappear if the drug be vigorously pushed. In this connection the statement of Bryson[5] is of value. He says that from his observations the size of the dose bears no relation to the frequency of the toxic effects. The most dangerous case of iodism seen in his practice followed quickly upon a three-grain dose. Taylor[6] states that in many cases of syphilis small initial doses have produced mischief, while succeeding larger ones have been acceptable, and also that in healthy subjects an intolerance of to-day may be replaced by a condition of assimilation a month, a year, or several years hence.

Another aspect of iodism is seen after long continuance of the drug; in this instance there is apparently no unusual susceptibility to its untoward effects, but the symptoms appear to be due to the dosage having been increased beyond what we may call the maximum iodine point of the patient. In these cases the relief of the coryza, etc., is but a simple matter, as by diminishing the dose and ascertaining the maximum amount the patient can stand the symptoms promptly disappear, not to return, provided the dosage be kept within the safety limit.

An almost cumulative effect is occasionally observed in the production of disagreeable or even serious symptoms relative to the upper air tract after the drug has been completely withdrawn for some time. In such instances no untoward symptoms having been present, yet they appear several days or weeks later, while in a somewhat larger class the drug has been withheld on account of mild iodism and within a short time severe symptoms develop, these latter symptoms often exceeding in intensity the former. This is especially pertinent to adults, as iodism is of exceptional occurrence in children, the younger the individual, the less being the liability to this accident.[7] The drug, in adults, seemingly has a specific action on the mucous membrane of the upper air paths, a single dose frequently producing a transient coryza and congestion of the palate and pharynx.

The tendency of potassium iodide to produce untoward symptoms of the respiratory tract is shown by the frequency of laryngitis and a low grade of edema in a considerable number of patients to whom the drug is administered. The severe form of glottic edema occurs without apparent reason, the general condition of the patient having little or no influence in its production, for it occurs in both the weak and robust without selection. Usually edema is not observed following large doses or after long medication, but it sometimes takes place after small doses and is the only symptom, none of the usual phenomena of iodism being present at the same time. The edema may be so extensive as to call for tracheotomy or suden death may even result. It may develop quite rapidly and may as suddenly disappear. Groenouw[8] reports a case that developed following a dose of only three grains of the drug and remarks that it may occur during the early administration of the drug; it being apparent that the longer the salt is used, the less is the danger of edema. An interesting case is reported by Heymann[9] in which edema developed in a syphilitic several days after the potassium iodide had been stopped; eight days later it disappeared.

The production of iodism in one individual and not in another, under apparently the same conditions and especially with small doses, has most frequently been explained by using the term idiosyncrasy. That certain individuals possess irregular reactions to some drugs is too well known to require any emphasis and in respect to the drug under consideration several theories have been advanced; that it is due to impurities, the most frequent being iodate of potassium; another that it is produced by defective renal elimination; while that of Capitain[10] is that iodism is due to the elimination of iodine by the various mucosa of the body. This phase has been studied by Ehlers[11] who found that the amount of potassium iodide eliminated by the urine was increased in proportion to the dose administered, iodism being caused by its retention in the body and occurring when only half the amount given had been eliminated. In cases in which doses of twenty grains are administered, it is eliminated in the proportion of seventy-five per cent.; there is no danger provided the excretive power is to some extent normal. While this explains the production of untoward symptoms from the ingestion of medium or large doses, it fails when applied to those cases in

which the symptoms are the result of minute doses.

I cannot agree with the theory of Rohmann and Malachowski,[12] *i. e.,* that in order that iodism can arise it is essential that nitrites must circulate in the blood and that the reaction of the mucous membranes must not be alkaline. A recent explanation, and to some extent plausible in the trend of the present study of internal secretion is that of Von Cyon[13] who, in studying the peculiarity expressed by the production of iodism following small doses, found that the iodine salts circulating in the blood were changed into iodothyrin through the influence of the thyroid gland and this substance produced a reaction. If on the contrary the iodides are administered in large doses, they act as diuretics and are promptly eliminated by the kidneys in the form of soluble salts.

Owing to the extensive use of iodide of potassium in all branches of medicine, a few words directed to the means of avoiding unpleasant phenomena may not be inappropriate. When the drug is administered in ascending doses for long periods, it is to a certain extent possible to prevent these phenomena by the conjoint administration of other drugs, such as arsenic and belladonna. While without these, symptoms of iodism may sometimes be prevented or the intensity diminished by varying the salt used, these results are enhanced if the alimentary canal is looked after and the patient is instructed with regard to the use of food and alcohol. The chances of unfavorable symptoms are decreased by dilution with water or milk. If it is taken in large amounts with little fluid it is retained much longer in the body than otherwise, whereas if liquids in copious amounts are freely exhibited, elimination is facilitated and at the same time favorable results are obtained.

CLINICAL MEMORANDUM.

A RARE CASE OF INJURY TO THE MEMBRANA TYMPANI.

By THOMAS D. TUTTLE, M.D.,
OF HELENA, MONTANA.

The following case is of interest on account of the rapidity of such injuries and the little trouble which resulted from so grave an accident.

Miss N. F., aged sixteen years, was referred to me by Dr. Dean with the following history: The patient, who had gone to bed with her hair "done up" with hairpins, on turning over suddenly in the night was awakened by a severe, sharp pain in the left ear and on placing her hand to her ear found a hairpin protruding from the canal. Her sister, who removed the pin, said that it was quite difficult to pull it out. Its removal was followed by some bleeding and the patient immediately fainted. It was also said that the patient's mouth was drawn to the right side. The pin had entered open end first, not the round end which is so commonly used by women to "explore" the auditory canal.

Although I questioned the patient's family, as as well as her physician, I could get no evidence of any hysterical tendency, nor did I notice any while she was under my care, but I am totally at a loss to understand how a hairpin could follow the course this one did without a hand to guide it.

On examination I found a punctured wound in the antero-inferior wall of the canal about half an inch from the membrana tympani, the course of which could be followed by a distinct red line almost to the membrane, although it grew less distinct as it approached the membrane. Slightly above the center of the tympanic membrane there was a small, round opening from which bloody serum escaped. The membrane appeared almost black and bulged slightly, so I concluded that the cavity was filled with blood. There was tenderness about the tragus and on moving the auricle. The use of the speculum caused severe pain. Hearing was reduced to the watch tick at two inches. The mouth was not drawn to either side.

On account of the probable septic condition of the instrument causing the injury, I fully expected that infection would result and a generally bad condition develop. I treated the case on antiseptic principles and at the end of eight days there was not any evidence of injury except a slight congestion of the membrana tympani about the point of puncture (which had healed), the membrane presenting a normal appearance with all the landmarks showing distinctly. The tick of a watch could be heard at seven feet.

MEDICAL PROGRESS.

Treatment of Urethral Strictures.—R. Harrison (*Lancet*, August 11, 1900) claims that in operations on the urethra, too often the fact is overlooked that this canal conveys for several inches at varying intervals a compound and complex fluid, which under certain conditions, not clearly defined, is capable of exercising a highly poisonous effect on the tissues and fluids of the body with which it may come in contact; thus we have rigors and fever, suppression of urine, and even septicemia. Operations on the strictured urethra produce results similar to accidental inju-

ries of a normal urethra; thus we have a lacerated or contused wound of the urethra when divulsion as practised in Perreve's or Holt's operation is employed; here the break in the tissues is at its weakest point, and the mucous membrane is torn and lacerated as in any traumatism; hence we are apt to have a recurrent stricture of persistent form; whereas in periurethral or submucous strictures, the dense bands are ruptured without necessary injury to the mucous membrane; hence a permanent cure may result. We produce an incised wound within the urethra in doing an internal urethrotomy; if the operation be carefully and properly done so that the entire thickness of the stricture can be included within the incision of moderate dimensions, a permanent cure may be effected, without being necessarily dependent on the subsequent continued use of sounds, although the practice of using sounds at intervals after the operation is advisable as a precautionary measure. The tendency to relapse is greatest where the internal urethrotomy has caused a ragged laceration rather than a complete incision of the strictured tissues; multiple strictures or strictures of the deep urethra treated by internal incision have a tendency to recur. We produce an incised wound of the urethra from without when external urethrotomy is performed; here, too, the permanent good results depend largely upon our technic; the operation should never be performed without a guide. Repair is necessarily slow owing to bathing of the wound with urine and the excessive exudation about the seat of the wound; the tendency to re-contraction and recurrence of all strictures after urethrotomy is diminished by the concurrent employment of systematic and efficient urine and wound drainage, such as the combination of external urethrotomy or perineal incision affords.

Poisonous Snake-Bites.—A description of the various poisonous snakes, together with a detailed consideration of their poison apparatus is interestingly given in the *Medical Record* (September 15, 1900) by G. Langmann. The effect of the snake-bite, the symptoms produced and a review of the many methods of treatment that have been used, make the article a very valuable one. The object of treatment is fourfold, to prevent absorption of the poison, to destroy or neutralize it, to accelerate its elimination and to treat symptoms of imminent danger. If the limb affected, as a finger, is not immediately amputated an Esmarch or other bandage should at once be used and the circulation relieved only to prevent gangrene. Scarification or better, either excision or destruction of the area by cautery is advised. Locally supposed specifics have been much used, as carbolic acid or permanganate of potash A solution of hypochlorite of lime, 1/60, has been found very effective by Calmette and is probably the best local remedy. Ammonia and strychnine act, doubtless, merely as general stimulants, but they are certainly of value. The poison exerts both a hemolytic action on the blood and a destructive influence on the cells of the medulla. To neutralize these actions a specific antitoxin must be obtained. Calmette and Fraser have offered to the world an antivenomous serum which experimentally has been shown to have the power of neutralizing lethal doses of the poison injected into animals, and has been used on man successfully in several cases. The antivenene is made by inoculating horses with a mixture of poisons from several species of deadly snakes after the hemolytic agent of the poison has been eliminated by heating to 80° C. It acts as a full protective in a dose of from 5 to 20 cc. when injected even one and one-half hours after the introduction of the venom. The action of the antivenene is supposed to be entirely chemical for a certain amount counteracts a miminal lethal dose when injected at separate points, but 1/1000 of this quantity is effective when mixed with the venom and injected. Phisalix of Paris has recently discovered that in the blood of some animals, as the eels, there is a substance which exerts a decided antitoxin action. Cholesterin, separated from biliary calculi and carrots, has a similar effect. The most commendable treatment is: Ligature of the part, scarification and injection of the antivenene, or, if not at hand, the solution of hypochlorite of lime; stimulation, artificial respiration for hours, if necessary; lavage of the stomach to remove the poison which is there secreted, and encouragement of the victim, for a deep mental prostration accompanies the depression of the nervous centers.

Treatment of Infantile Eczema.—In the squamous or the milder grades of papular or vesicular eczema of children, L. Leistikow (*Monatshft. f. prak. Dermatolog.*, September 1, 1900) recommends the use of a zinc-oxide paste containing one to two per cent. of yellow oxide of mercury. In eczema rubrum or crustosum nothing seems to act so well as a plaster mull with zinc oxide and ichthyol. It is only in the most obstinate cases that this treatment fails when resort must be had to pyrogallic acid, which never disappoints. It is best applied incorporated in casein ointment and, if not used stronger than two per cent., no ill effects will ensue.

Optic Neuritis in Chlorosis.—Optic neuritis is occasionally seen in chlorosis, but cases are rare in which it dominates the clinical picture to such an extent as to lead to a wrong diagnosis. The patient in the case reported by A. Engelhardt (*Münch. med. Woch.*, September 4, 1900) had but a moderate diminution of hemoglobin and red cells. There was, however, complete blindness, with headache, anesthesia, paralysis and other nervous symptoms to such an extent that the diagnosis of brain tumor seemed without question, especially when later in the disease localizing symptoms in the form of epileptic convulsions appeared. The autopsy revealed nothing but extreme dryness and anemia of the brain tissues, and left only anemia to explain the symptoms.

THERAPEUTIC HINTS.

Sciatica.—According to Weir Mitchell (*Clinical Lessons on Nervous Diseases*) sciatica pain tends to be worse at night, therefore the treatment should especially cover this period. Certain sciatic cases are eased by exertion, but a true sciatic neuritis is usually very painful on walking or when the nerve is stretched by sitting, or going up stairs. The treatment followed is rest in bed, constant and prolonged, until recovery is assured, and dry cupping. About three dozen cups are applied in a double or triple row around and over the sciatic notch and down the leg. They are left on for half an hour and may be repeated the next day and two days later. In lieu of this, a mustard plaster, three inches wide from notch to knee or to ankle, may suffice. With chronics of long standing, cocaine injections, ¼ to ½ grain, may be needed at first. A splint to prevent motion at hip and knee, and a firm flannel bandage from foot to groin are applied and changed twice a day. In some intractable cases ice-bags may be added. Later, as the pain fades, the joints are mildly and passively exercised and the leg gently massaged once a day. After about three weeks the splint is left off in the daytime, but the bandage continued. Meanwhile the general condition is improved by cod-liver oil, iron at need, good diet and care of the bowels; effort at stool should be prevented by hot enemas. Persistent painful points are treated by the Paquelin cautery or a small blister. When the patient first gets up, motion and the pressure of the hard edge of a chair or wooden stool are likely to bring back pain, hence he must not sit at all the first week, but must stand or walk with the aid of crutches or else lie in bed.

Angina Pectoris.—Wm. Osler (*Angina Pectoris and Allied States*) discusses the treatment under four headings. (1) General management; treat syphilis, gout, diabetes, or valvular lesions; emphasize the importance of the three great factors in causing attacks, *viz.*, mental worry, exercise, and diet; warn against sudden movements which throw a strain upon the heart, and encourage steady, quiet exercise. For diet, have meals light, limit amount taken and exclude rich, highly seasoned, or easily fermentable food. Above all things avoid flatulency. This may be relieved by hot grog in elderly people, peppermint, spirits of camphor, Hoffmann's anodyne, carbolic acid, iodine, or creosote. Hot water before meals, a few doses of blue mass, an occasional saline purge, and the use at times of a bitter tonic keep this condition in check. Intestinal disinfectants, such as salol, betanaphtol, or grains 1/60 to 1/30 of corrosive sublimate may be helpful. (2) General medicinal treatment; genuine angina in a man under thirty five years demands vigorous antisyphilitic treatment. In gouty cases free elimination by bowels, skin, and kidneys, proper diet, and at intervals a course of colchicum, are desirable. The routine treatment consists of iodide of potassium, 10 to 15 grains three times a day, for from two to four years. This is contraindicated in advanced arterial degeneration, dilated heart, and interstitial nephritis. In hypertension give tablets of nitroglycerin, 1/100 grain, increased slowly to four or five at a dose, or sodium nitrite, 5 to 10 grains; in feeble heart with anemia, give iron, arsenic, and strychnine. (3) Treatment of the attack; nitrite of amyl, two to five minims, gives prompt relief in some cases, but is singularly uncertain. Morphine hypodermically, in quarter-grain dose, repeated if necessary, is the most useful drug. It relieves the distress and steadies and improves the heart's action. While waiting for these drugs to take effect, chloroform may be dropped upon a handkerchief and inhaled. (4) Treatment of the complications; for syncope, aromatic spirits of ammonia, Hoffmann's anodyne and brandy by mouth, and hypodermics of camphor or ether; for the cardiac dilatation and weakness, nitroglycerin with strong friction of the limbs to increase the peripheral circulation, and digitalis or digitalin, caffeine, and camphor for the heart's action. If these measures are futile, puncture of the heart may arouse to quite vigorous action a dilated and paretic organ. For the dyspnea and Cheyne-Stokes breathing strychnine, 1/40 to 1/20 grain, hypodermically, three or four times a day, and blisters to the precordium and to the bases of the lungs, may give relief.

Hyperidrosis.—The *Journal de Médecine de Paris* gives the following formula for use by persons afflicted with hands and feet that perspire too freely:

℞	Borax	15.0
	Acid. Salicyl.	15.0
	Acid Boric	4.0
	Glycerin	60.0
	Alcohol (dil.)	60.0

M. Sig., apply with friction three or four times daily.

For Ringworm.—The *Journal de Médecine de Bordeaux*, July 29, 1900, gives the following formula of which the active ingredient, epicarin, a condensation product of betanaphtol and cresylic acid, is recommended by Kaposi:

℞	Epicarin	5i
	Talci Veneti	5i
	Amyli	5i
	Vaselini	5iii.

M. Ft. unguentum. Sig., external use.

Phlebotomy for Varicose Ulcer.—*Bachmard* (Ilfeld), after noting marked improvement in such ulcers subsequent to hemorrhage near the same, tried the effect of blood-letting in thirteen cases and found that cicatrization was greatly hastened thereby. In two cases the vein selected was opened directly at the site of the lesion; in the others it was in the neighborhood. From three to ten ounces of blood were withdrawn, according to the vigor of the patient.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

THE PATHOGENY OF GOUT.

IT is an interesting index of the perennial freshness of problems dealing with the causes of human suffering to find the pathogeny of gout at the head of the program of the Thirteenth International Congress of Medicine, held in Paris last month.

The pathogeny of gout is a subject which has engaged the attention of both clinical and laboratory investigators from time immemorial and has probably given rise to more speculation than any other question with which the medical man is called upon to deal.

The protean character of typhoid is well recognized, but compared to the manifold manifestations of gout the comprehension of the former disease is a matter of childlike simplicity. A mere glance at the literature of gout is enough to overwhelm one by its very infinitude.

Through the labors of physiological chemists we know that the materies morbi—the peccant matter—which causes gout is uric acid or certain of its derivatives, but its exact modus operandi continues to elude even the most refined methods of laboratory research. This throws the burden of explanation of the pathogeny of the disease upon the clinicians; in other words, renders the subject one of pure speculation.

Fortunately for us, the disease is not common in America, so that at present we have little opportunity either for extended clinical observation or for the speculation to which such opportunity seems inevitably to give rise. The very youthfulness of our civilization is our safeguard from the malady; but, alas, even so young a country as ours will grow old sometime, and we may look confidently forward to the day when our golden and gout-free age will give place to a gouty and speculative one.

In England and continental Europe, where civilization is already centuries old, the speculative tendency with reference to the pathogeny of the disease under discussion has been rife for more than a hundred years. Even before the days of animal chemistry gout was believed to be due to a perversion of physiological function, the result of which was certain "peccant matters" which were supposed to be distilled into the joints. This was the so-called "humoralistic" doctrine, and it held sway with practical universality until Cullen introduced the "solidistic" theory that "gout was an affection of the nervous system in which the primary moving powers of the whole system are lodged."

From Cullen's time to the present the terminology of theorists has become more scientific, perhaps, but it can hardly be said that we are appreciably nearer to a clear understanding of the problem of pathogenesis. Experts in the matter all over the world seem now to be in accord as to the paramount importance of the pathogenic rôle of uric acid in the disease, but just how this acid gets its origin and does its mischief is a question which remains in all its old-time obscurity. We are assured that heredity is a predisposing factor of vast importance and that, given this factor, combined with the peculiar vice of nutrition to which it inevitably leads, we may confidently look for uric acid and gout in certain members of a family. But just what the factors are which originate the causal nexus between the peccant matter and its clinical manifestations promises to remain a fruitful source of speculation.

At this point a word as to the diabolical malevolence of gout may not be out of place. Unlike syphilis its transmissibility does not wane with a person's age. On the contrary the first children begotten by a goutily-disposed parent may escape the inheritance of the diathe-

sis, while with succeeding offspring the danger of its inheritance increases so constantly that the cadet of the family—in countries where the law of primogeniture prevails—has little to expect from paternal bounty outside of an organism which in time will yield him a fine line of uratic tophi, to say nothing of a chronic interstitial nephritis.

To sum up in a word the modern theories of the pathogeny of gout, they embrace the most plausible ideas of the humoralists and solidists combined; that is to say, they admit "peccant matter"—uric acid and its derivatives—which exert their noxious influence upon the economy, in part, at least, through nervous or trophic influences.

Viewing the subject broadly, but little objection can be offered to such theories, but we cannot refrain from expressing a certain degree of surprise at finding that one very noted exponent of the neuro-humoral theory who took part in the discussion at the International Congress, Sir Dyce Duckworth, still persists in locating the neural origin of the disease in the bulb. When this celebrated English author published his well-known treatise on gout several years ago, he then expressed the opinion that there was a bulbar center which had to do directly with the trophism of joints. This opinion he based on the fact that a certain observer, whose name now escapes us, found bulbar sclerosis in a case of locomotor ataxia which had been marked during life by the presence of that peculiar trophic disturbance in the joints known as tabetic arthropathy.

Now, from our present advanced knowledge of the anatomy, physiology and pathology of the nervous system, it is at once obvious that a bulbar center having any such specific function as Dr. Duckworth claims can only exist in the realms of fancy, and we are sorry to find him still retaining such a weak link in his chain of reasoning.

After all has been said, it cannot be denied that the pathogeny of gout is a most attractive subject. The truth of this is obvious from the fact that it has drawn to its study many of the brightest minds that have adorned the profession since the time when the disease first began to menace the well-being of humanity. Nevertheless we cannot refrain from saying that we believe the problem to be one which will continue to rear its sphinx-like countenance to numberless medical generations yet unborn.

OYSTERS AND INFECTION.

From the earliest times more or less suspicion has been cast upon shellfish—chiefly oysters and mussels—as being the cause of outbreaks of disease among consumers. For the most part these have been cases of sudden poisoning due to the presence of putrefactive products in the molluscs and diseases due to a specific micro-organism, where there is a period of incubation and where, therefore, a considerable interval has elapsed between the time of entrance of the germs into the body and the actual manifestations of the illness. In the latter case it is obviously far more difficult to establish the source of infection; and despite the frequent positive assertions crediting certain epidemics of typhoid fever to the consumption of oysters, it must be confessed that the alleged association of cause and effect in these outbreaks has more popular support than scientific demonstration. And yet, notwithstanding the absence of the clinching evidences of absolute proof, there is much in the connection between the two which makes it a possibility, indeed, a probability.

During recent years much public interest and apprehension have been raised by several outbreaks of enteric fever popularly attributed to oysters, such as that of the Wesleyan University in Connecticut, investigated by Professor H. W. Conn in 1894; that of Stirling Ball in October, 1895; and that in the south of France reported on by Dr. Chantemesse in 1896. It has been apparent from these and numerous other similar epidemics that the condition under which the shellfish were liable to contamination with sewage, and thus became the carriers of pathogenic organisms, required investigation. Studies pursued along these lines by Professor Herdman, of the Lancashire Sea-Fisheries Committee, and Dr. Boyce, of University College, Liverpool (*Thompson-Yates Laboratory Report,* Vol. 2, 1900), have thrown much light upon this important problem, the far-reaching significance of which cannot be too strongly emphasized.

Some very instructive and interesting experiments were made by these investigators on the feeding of oysters with normal feces and the feces of patients suffering from typhoid fever. It was found that oysters could, up to a certain point, render sewage-contaminated water clear, and that they could live for a prolonged period in water rendered completely opaque by the addition of fecal matter; that the fecal matter obtained from cases of typhoid was more inimical

than that obtained from healthy subjects. The results of the bacteriological examination of the pallial cavity of the oyster and of the contents of the rectum showed that in the case of those laid down in the open waters of the Bay the colonies present were especially small in number, while in those laid down in proximity to the drain-pipe of a town the number was enormous. In the case of the oysters grown in waters infected with the bacillus typhosus, it was found that there was no apparent increase in the organisms, but that they could be identified in cultures taken from the water of the pallial cavity and rectum fourteen days after infection. It was further determined that the bacillus of typhoid fever would not flourish in clean sea-water, and the experiments seemed to show that it decreased in numbers in its passage along the alimentary canal of the oyster. It would seem probable, then, that by methods similar to those employed in the *bassins de dégorgements* of the French ostreiculturists, where the oysters are carefully subjected to a natural process of cleaning, oysters previously contaminated with sewage could be freed of pathogenic bacteria or their products without spoiling the oyster for the market. Thus in a series of tests with oysters infected with the typhoid bacillus and subjected to a running stream of clean sea-water, the results were definite and uniform. There was a great diminution or a total disappearance of the germ in from one to seven days. Under ordinary conditions the colon group of bacilli is commonly present in shellfish as sold in cities, and especially in oysters—a finding which naturally suggests sewage contamination.

It need scarcely be remarked that if it becomes possible to cleanse infected oysters by a simple mode of treatment, such as that just mentioned, which will render them innocuous, a great boon will have been conferred upon both the oyster-trade and the oyster-consuming public. Those in charge of matters of public hygiene will find in this a theme for consideration.

PENNSYLVANIA STATE MEDICAL SOCIETY.

THE fiftieth annual meeting of this society held last week at Wilkes-Barre was a most successful one. The fact of there being an important strike in progress did not interfere either with the social or scientific features of the meeting, both of which were thoroughly enjoyable. To the Luzerne County Medical Society the success of the former is due. The latter were made manifest in a most varied program of papers of high value. The address of the President, Dr. George W. Guthrie of Wilkes-Barre, while on a subject so well gone over, was presented with a force and fervor worthy of its reader.

Several features stand out in the program which are worthy of emphasis, coming as they do from this, one of the oldest State medical societies of this country. The subject of water pollution and its municipal and State control was discussed quite thoroughly. It is to be regretted that the clashings of authorities shoud continue to stand in the way of effecting much needed reforms along these lines, yet such is the case in this as well as in many other States.

In the address on obstetrics by Dr. Noble of Philadelphia the significant fact was brought out that, although there had been a most marked reduction in the mortality among women in childbirth in the cities of this country, a like reduction could not be shown for the women of country districts. This would seem to indicate that efficient aseptic midwifery is not as widespread as it should be. He also spoke of the gradual and long-looked-for return to conservative surgery of the female generative organs. It is to be hoped that the era of reckless abdominal surgery in woman has been permanently ended.

In the symposium on typhoid fever Dr. H. A. Hare recurred to the important topic of variations in this disease. He emphasized the importance of recognizing the cases with sudden acute onset, and said that typhoid fever is much more commonly aberrant in type than is usually taught. He further brought out the interesting fact that the recent great increase in typhoid fever, due to the Spanish war, was accompanied by a very marked decrease in the already decreasing death-rate from this disease. Dr. Stengel, in discussing the treatment, plead for a wider choice of individual therapeutics. While the Brand method has undoubtedly given most excellent results, it is not necessarily to be used to the exclusion of all other modes of treatment. The use of camphor was recommended by him quite highly. This stimulant has long enjoyed a popularity with some practitioners and it has become once more a fashion to use it in place of, or as synergist to, alcohol. It undoubtedly deserves wider use.

These with other papers were widely discussed at the meeting which was attended by over 300 members. We present a complete report to our readers in this week's issue of the MEDICAL NEWS.

ECHOES AND NEWS.

NEW YORK.

Densest Population.—The daily press announces that the block bounded by Sixtieth and Sixty-first Streets, Tenth and Eleventh Avenues, New York, is the most densely populated block in the world. The new census shows it to have 6888 inhabitants.

Tuberculosis and Notification.—Dr. Black, Assistant Sanitary Superintendent of the Borough of Brooklyn, says that at least fifteen physicians in that borough have failed to report cases of tuberculosis. He has had one arrested and intends to make a test case.

Water Famine.—Should the present drought be unbroken, Brooklyn and the Bronx will suffer severely from the scarcity of water. Sensational newspaper articles are claiming a great increase in typhoid and malaria. The connection of the latter with diminished water-supply, or even the former, is difficult to trace.

Use of Soft Coal.—Dr. F. H. Dillingham, Assistant Sanitary Superintendent, reports that the Board of Health as yet has no outlined policy in regard to the enforcement of the ordinance against the use of soft coal. This ordinance is directed not really against the use of soft coal but against the increased amount of smoke caused by the use of it. As long as the smoke does not pass a certain limit the Board does not know or care how many factories use soft coal. In the present strike emergency the Board of Health does not intend to interfere with the industries of the city. But any attempt to use the cheaper coal indefinitely at the expense of the purity of the air will be checked.

Hospital for Consumptives.—Subject to the approval of the State Board of Health and the Forest Preserve Board the Commissioners of the new State Hospital for Consumptives have selected a site at Big Clear, near Saranac Inn station. The commission consists of Howard Townsend, Dr. John H. Pryor, Dr. Willis S. Macdonald, Walter Jennings and Frank E. Kendall, and their decision was reached at a meeting held at the Fort Orange Club in Albany. For reasons which were chiefly sentimental the site at Dannemora, which was the subject of a recent commendatory report by Commissioner Montanye, of the State Prison Commission, was not selected. Of the Big Clear site it was said in objection that it is near a large body of water and subject to heavy rainfall. The commissioners, however, felt that they did not care to associate their hospital with a locality in which a prison is situated, and decided on the more expensive site. It is understood that the two bodies that are to pass finally on the matter do not like the selection either from an economical or a sanitary point of view.

Malaria and Garbage.—An epidemic of malarial fever has broken out on Coney Island, and over 300 cases have been reported from various parts of the island. On one street thirty-six families were afflicted and the physicians in the neighborhood have their hands full. Dr. John F. Hill, of Gravesend, reported 140 cases, Dr. John F. Pierce 185 cases, and Dr. Sigmund Peck 60 cases. It is said in Coney Island that the epidemic is the result of the dumping of garbage from Brooklyn on the west meadows along Coney Island Creek. Last week sixty-five carloads of refuse were dumped on the meadows, and the residents of Coney Island are up in arms. The contractor who has had the garbage dumped on the meadows was arrested twice, but when arraigned in the Coney Island Police Court was discharged on both complaints. Dr. Hill says that the dumping of garbage on the meadows is an open violation of the laws relating to the disposition of city refuse. Mosquitoes are in great abundance about the garbage.

Havana and Yellow Fever.—The present outbreak of yellow fever in Havana does not, in the opinion of Dr. Doty, the Health Officer of the port, involve any danger to this city. "The condition of affairs in Havana is very bad indeed," said Dr. Doty last week, "and the work of stamping out the yellow fever there is made difficult by a considerable number of cases that are not reported to the authorities. But here in New York we need not be afraid of it. The inspection at Quarantine is made more laborious for us, and we may find a fever patient or two; but the disease cannot live in this climate, and there is not the slightest danger of its spreading. In the course of another month the weather will have become so much cooler that even the Southern cities will have little fear of it. A good frost is a sure protection. But there is a very serious side to the matter, and one that cries out for action by Congress. General Wood has done all that human skill and energy could do with the means at his disposal. He has cleaned up Havana as it never has been cleaned before, and still the fever lives. And the fever will continue to live, and break out every summer, until $10,000,000 or $15,000,000 are put into a first-class sewerage system for Havana. The streets there now are not properly graded or paved, and many of the sewers, where there are any sewers, cannot carry off the waste that is poured into them. A house built on the best sanitary principles may be set over a choked sewer or sewage-soaked ground, and then all its fine plumbing is worthless. Nothing but a thorough system of new sewers and the removal of the wooden work on the waterfront can secure safety. Congress must do this work. The Cubans never will do it, for they are immune to the fever, and don't care. And besides that, they won't spend the money. It is of the highest importance, in my opinion, that Congress should take hold of this matter. Business reasons alone demand it. The

fruit trade is practically shut out from the Gulf ports during the summer, no one can come from Havana to this country by way of Florida, and even the shipping to New York is subject to serious delays ad restrictions. Havana must be made clean, and Congress must pay for the work." Over 100 cases of yellow fever are now under treatment in the city of Havana. During the month of August there were 54 cases with 49 deaths. The disease is practically epidemic.

PHILADELPHIA.

Obituary.—Dr. W. Scott Wolford, formerly coroner's physician, died September 18th after a long illness. He was associated in practice with the late Dr. Chapman.

Homeopathists in Session.—The thirty-sixth annual session of the Homeopathic Medical Society of Pennsylvania was held in Wilkes-Barre, September 25-27th. The Society is seeking the establishment by the Legislature of a hospital where insane patients may receive homeopathic treatment.

Company Physicians.—The strike of the anthracite coal miners has brought up a question which is interesting to the medical fraternity. The miners demand the abolition of company physicians, paid by the retention of a certain amount of their wages. Several of the operators state that such a rule is now enforced at very few mines, the miners being allowed to select their own physician.

Quarantine Station Wrecked.—To avoid collision with another boat the British steamer "Fallodon Hall" was run into the artificial island upon which is built the Reedy Island quarantine station. The accident occurred during a fog September 22d. The signal tower was carried away and the disinfecting barracks badly damaged.

The Duties of Parenthood.—Under the auspices of the Pennsylvania Society of Mothers a course of Monday afternoon lectures is to be given, beginning October 1st. The subject will be "Life and Education" and the aim is "to develop wiser and better-trained parenthood, to establish kindergartens and laws which will adequately care for neglected and dependent children, and to establish juvenile courts which will rescue instead of confirming children in evil ways." Men will be admitted to active membership in the Society.

Health of City Exceptionally Good.—The past week has shown a better health average than for the corresponding period of the last three years. One case of smallpox was discovered in the twenty-second ward. The only disease unusually prevalent is diphtheria, 101 cases being reported. A commission has been appointed to condemn land in various localities for the inauguration of filtering plants. The Mayor has suggested that in connection with these plots buildings might be erected to relieve the overcrowded condition of the insane wards of the Philadelphia Hospital.

Polities Charged with Continuing Nuisance.—The citizens at Thirty-seventh and Wharton Streets are vainly trying to secure the abatement of a nuisance in the shape of dust from two paving companies' plants. The plants were ordered closed by the Board of Health, but the order was ignored. A later report of the medical inspector practically ignored the plants. A councilman is part owner of one plant and the present Board of Health was appointed by the Mayor, the old board being abolished at his request. The matter has been carried to the courts by interested citizens.

Jefferson Medical College Hospital.—This hospital has responded nobly to the calls for help from the Galveston sufferers. Besides furnishing medical supplies, the first relief train sent out by the *North American* carried a physician and eight nurses from the hospital corps. A large tent has been erected and this improvised hospital bears the best record of any established within the zone of the disaster. The corps is under the charge of Dr. E. R. Kennedy.

State Medical Society Notes.—The oldest delegate present was Dr. J. A. Ehler of Lancaster. He is eighty years of age, was at the first meeting of the society, and is still in active practice. A special vote of thanks was tendered the Wilkes-Barre papers for the unusually accurate reports of the meeting.—The discussion on State laws elicited the fact that a school of osteopathy in Wilkes-Barre has 150 students, each of whom pays an annual tuition of $300.—The resemblance of the newly-elected President, Dr. T. D. Davis, to President McKinley led to a laughable incident Thursday. Dr. Baldy of Philadelphia impeached a certain member of the society, denouncing him in strong language for a breach of professional etiquette. The crime of the gentleman consisted in scattering broadcast through the town his own picture. When the society was in a high state of excitement the speaker uncovered a portrait of McKinley and the laugh was on Dr. Davis.

CHICAGO.

Elephantiasis.—A Mrs. Griswold, colored, recently died at the Cook County poor-house of this disease. Up to the time of death she weighed 500 pounds. It is said that her limbs were the size of an average man's body. For several months she practically lived in a chair. Her coffin was seven feet long, four feet wide, and three feet deep.

Arrival of Dr. Barker.—Dr. L. F. Barker, from the Johns Hopkins University, has assumed his duties as Director of the Department of Anatomy at the Chicago University and at Rush Medical College.

Drug Adulteration.—At a recent meeting of the Wholesale National Drug Association, held in this city, the manufacturers and jobbers who sell adulterated drugs were roundly scored. A

committee of the Association made the following recommendations: That we deprecate the sale of misbranded and adulterated foods and drugs; that we constantly keep before us the importance of quality in the products we sell, on many of which life is often dependent; that we reiterate our endorsement of the Brosius pure food and drug bill; that we label correctly and definitely all goods we sell; that we carefully consider the advisability of advocating the sale by assay, chemical or otherwise, of the drugs and medicinal products which contain alkaloids, resins, oils, oleoresins, and essential oils.

State Laboratories.—Dr. Frances Dickinson, President of the Illinois Educational League, is making an effort to secure from the State Legislature an appropriation of $50,000 to be used in establishing in Chicago and in other cities of the State laboratories for the teaching of the sciences of physics, chemistry, bacteriology, biology and microscopy, and for extension courses throughout the State in sanitary and agricultural sciences. It is intended that the laboratories shall be open in the evenings, to enable bread-winners to procure a higher education than they are able to get now.

Physicians' Club.—At a meeting, held September 24th, the requirements for admission to medical schools were discussed. The discussion was opened by Professor O. W. Small of the University of Chicago.

College of Physicians and Surgeons.—The following appointments have been made in this medical school: Dr. Harris E. Santee, Professor of Anatomy; Dr. John L. Porter, Professor of Orthopedic Surgery; Dr. Joseph M. Patton, Professor of Physical Diagnosis; Dr. Daniel N. Eisendrath, Professor of Clinical Anatomy; Dr. Don L. Shaw, Professor of Anatomy; Dr. Julius H. Hoelscher, Professor of Clinical Medicine; Dr. Bernard Fantus, Adjunct Professor of Materia Medica; Dr. August F. Lemke, Adjunct Professor of the Practice of Medicine; Dr. Edward H. Lee, Adjunct Professor of Practice of Surgery; Dr. James M. Neff, Adjunct Professor of Practice of Medicine; Dr. A. E. Baldwin, Adjunct Professor of Stomatology; Dr. Eugene R. Whitmore, Adjunct Professor of Chemistry; Dr. Samuel J. Walker, Adjunct Professor of Clinical Anatomy and Instructor in Surgery; Drs. Edward F. Wells, William K. Jaques, and James W. Walker, Adjunct Professors of Practice of Medicine; Dr. Leo Loeb, Assistant Professor of Pathology; Dr. William H. Rumpf, Instructor of Gynecology.

GENERAL.

Pollution of the Navesink.—The residents of Red Bank, N. J., are up in arms over the pollution of the river from which they derive their revenue. The oyster-crop is said to be rendered totally unfit for sale.

Bee-Sting Causes Death.—A death from the effects of a bee-sting followed by septic poisoning is reported from Paterson, N. J.

American Association of Obstetricians and Gynecologists.—The officers for 1901 were elected as follows: President, Dr. W. E. B. Davis, Birmingham, Alabama; First Vice-President, Dr. Edwin Walker, Evansville, Indiana; Second Vice-President, Dr. A. Goldspohn, Chicago, Illinois; Secretary, Dr. William Warren Potter, Buffalo, New York, re-elected; Treasurer, Dr. X. O. Werder, Pittsburgh, Pennsylvania, re-elected. Cleveland, Ohio, was selected as the place for holding the next annual meeting; time, second Tuesday in September, 1901.

Vienna University Changes.—Docents L. Königstein, Solomon Ehrmann, Jacob Pal, Emil Redlich and Anton Elschnig have been appointed "ausserordentlichen" Professors. Dr. Ludwig Braun has been appointed Docent.

The Xi-phopages Twins.—The Medical News of March 5th described the first operation on these twins Later reports show that Marie died as a result of the operation. Rosalina survived, however, and has just arrived in Paris where she expects to present herself to the scientific societies of that city and of the other European medical centers.

Poisoning by Laburnum.—The Bradford Cinderella Club of England recently took 600 children from the slums to the country. Some twenty developed symptoms of acute narcotic poisoning from eating laburnum pods. All of the children recovered.

Death from Canned Tomatoes.—A death in England is announced of a boy from eating canned tomatoes. The post-mortem evidence was conclusive.

Plague at Glasgow.—The situation at Glasgow has settled somewhat. After the temporary flare-up of last week the number of reported cases has fallen markedly. At the present time there are but forty suspects under observation; fifteen cases are being treated; seven deaths have occurred.

The Reformation of America.—The following charming bit is just received from England, although a trifle belated. *The Bristol Medico-Chirurgical Journal* of June makes the following comments regarding its own potent influence on the medical world. "Its circulation now extends from China to Peru. There is not a country in Europe where its influence is not felt. *It is reforming the American continent from Canada to the Brazils.*" We have been noticing the reform and are glad that we now know whom to thank.

Yale Notes.—Prof. George Trumbull Ladd, of the department of psychology and mental philosophy at Yale, has returned from his long tour among the national universities of Japan, India and Egypt. He visited the Paris Exposition in

August as an American delegate to the International Psychological Convention.

New College Buildings.—Several important new buildings are to be opened soon at leading educational institutions of New England. It is reported that the Harvard medical school will be moved to Brookline soon. The medical, veterinary and dental departments, now in various parts of the city, will be united and equipped with a museum and new laboratory. The future school with its grounds will cover twenty-seven acres and will cost $1,000,000.

Science and Pharmacy.—During the recent International Congress of Pharmacy held at Paris a monument was unveiled to Bertrand Pelletier and J. B. Caventon, who are celebrated as the discoverers of brucine, strychnine, and quinine. These two renowned pharmaceutical chemists, when they had discovered quinine, immediately presented the results of their investigations to the Paris Academy of Sciences on September 11, 1820, thus placing this important drug at the command of the medical profession. Instead of keeping their discovery secret, they published a full account of their methods and results, and stated how they had been able to isolate cinchonine and quinine from both yellow and red cinchona bark, and also added their observations on the therapeutic properties of these substances. For their discovery and the valuable services rendered to science they received the Montyon prize of the Academy of Sciences, and the monument now erected is a further testimonial to their services to science and humanity.

Railroad Disinfection.—The Cleveland, Cincinnati, Chicago and St. Louis and the Chesapeake and Ohio will make experiments with new railroad coaches, which are to be constructed on a more sanitary principle than the present carriages, conforming as nearly as possible to recommendations of the Railway Surgeons' Association. According to the views of this organization, there are many things in the modern coach which tend to catch and retain dirt and filth, and which offer hiding-places for many disease germs. The plainer the build inside and the fewer decorations and fineries a coach contains the better it is for the travelling public. Sanitation, it is alleged, has been sacrificed to comfort. Plush seats and carpets on the floor are especially objectionable. Steam-pipes should remain uncovered, and fancy cornices and filigree work on sides and ceilings should be done away with. The reception of these cars by the public will be watched with interest by all the railroads, as their success will mean a great saving of expense and trouble to the roads.

Doctors Combine.—The Physicians' Business Association, recently organized in Detroit, would be more appropriately called the Detroit Physicians' and Surgeons' Union No. 1, *The Tribune* of that city says. In intents it is a union, its chief object concerning wages. "If any employer refuses to pay his doctor, or insists on compensating him with wages below the union scale," *The Tribune* explains, "the doctor will strike, just as the miners have struck—that is, he will refuse to treat him any more, refuse to work for him. All the other union doctors must likewise strike, and refuse treatment to the employer who refuses honest pay for honest service." At the first meeting of the Association there was violent talk on a proposition to boycott doctors who should refuse to join the Association. A section of the constitution offered for approval went so far as to provide that Association members should refuse to recognize as physicians, either personally or professionally, such boycotted doctors. There was at first some objection to so radical a measure, but the vote showed that the sentiment favored it in overwhelming measure.

Drunkenness in London.—A parliamentary return on the working of the Inebriates Act, under which the Magistrates are able to commit habitual drunkards to inebriate reformatories, discloses the startling fact that of ninety-two such convictions ninety were women. Such convictions would be more numerous but for the fact that State reformatories do not exist, but it is significant that of the six institutions existing five are for females. Within the London Metropolitan police district there are 11,000 public houses. The temperance reformers say that this oversupply is greatly responsible for the fact that there were 46,899 arrests for drunkenness in London in 1897, but whatever may be the moral effect one result of the great number of licensed liquor shops is certain, *viz.*, the hindrance of street improvements in London, for the value of the licenses in addition to the cost of acquiring property must be paid by the rate-payers. An example of the seriousness of this cost is seen in the case of an avenue now being made connecting the Strand with Holborn. The purchase price of liquor licenses along a route of less than half a mile in length was over £100,000. This has been the cause of the abandonment of many desirable improvements in London.

Obituary.—Dr. I. Zacharie, an old resident of New York but established in London as a chiropodist and bonvivant, has just died in London.—Dr. Richard H. White of 120 West Forty-eighth Street, died of phthisis in Liberty, N. Y., September 22d at the age of thirty-two years. He graduated from the University of Toronto and devoted his time subsequently to the study of tuberculosis. Dr. White leaves a widow and one daughter.—Dr. Max Schaeffer of Bremen, specialist in diseases of the larynx, died recently while making an Alpine tour.—Dr. Preston B. Scott of Kentucky died Monday, 24th, aged sixty-eight years. Dr. Scott came of an old Kentucky family. His father was a prominent figure in Frankfort in which place Dr. Scott was born. After the war Dr. Scott settled in Louis-

ville and became widely known throughout the State. He was President of the Association of Physicians and Surgeons of the Confederate Army and Navy. He has a brother who is also a physician.—Dr. James Hart Curry, who had practised medicine for over fifty years in Westchester and Putnam Counties, died recently at Shrub Oak at the age of seventy-three. He was educated at the Peekskill Military Academy and the Yale Medical School, from which he was graduated in 1852. He served in the war as a surgeon in the Eighteenth Regiment, New York Volunteers. For some years he was President of the Yale Medical Alumni Association.

Pasteur Institute in India.—David Semple, M.D., major in the British Army Medical Corps, formerly assistant professor of hygiene at Netley, the first officer appointed to the Pasteur Institute in India, opened recently at Kasauli, and he will assume the chief superintendence.

Electricity in Medicine.—The tenth annual meeting of the American Electro-Therapeutic Association was held this week at the New York Academy of Medicine.

American Public Health Association.—The twenty-eighth annual meeting of the Association will be held at Indianapolis, Indiana, beginning October 22d and continuing until October 27th. A long and varied program is announced.

Risked Life for Diploma.—Dr. Lester Winn of Borough Park, Brooklyn, nearly lost his life September 25th, while attempting to save his diploma of the College of Physicians and Surgeons from his burning residence at Fourteenth Avenue and Fiftieth Street. When the fire was first discovered it was with difficulty that the doctor and his two servants were aroused and carried out by the firemen. A few minutes later Dr. Winn rushed back in the burning cottage for his diploma, which was in the front room on the second floor. He succeeded in finding it, but while groping about the lower vestibule was overcome by smoke. Fireman Cantwell found the physician unconscious on the floor and dragged him to the open air, where he was revived. The diploma was recovered, after the fire had been extinguished, near the spot where the doctor had fallen unconscious.

Identification of Criminals.—Through an arrangement made at Cleveland, Ohio, this week, between Superintendent of Prisons Collins and the representatives of nearly all the penal institutions in the United States that use the Bertillon system of identification, the State central bureau of identification at the capitol in Albany will be used as the central bureau for all these institutions. It is hoped by such an interstate system that the identification of criminals will be facilitated and life and property will be more secure.

OBITUARY.

The life of a physician makes perhaps the most interesting of all biographies. And those who are themselves physicians know what it means to have lived a life of increasing fame. Between the lines that are crowded with mention of honors and success, they can read the long years of patient preparation, the steady enthusiasm, the persistent effort, the untiring patience that have made their names great.

It is like reading a death-roll of heroes to see in the same obituary columns the deaths of three such famous men as Dr. Hunter Holmes McGuire, Dr. Lewis A. Sayre and Dr. Alfred Stillé. All were elderly men, the last two very old. All were men of world-fame, and all will be mourned by their profession.

DR. HUNTER HOLMES McGUIRE

When a man is not only a physician, but a soldier, a scientist and a patriot, when he has seen thrilling service in wars, when he has made advances in the world's science, and when he has associated himself intimately with affairs civic, the life reads more like a novel than a biography. Such a man was Dr. Hunter Holmes McGuire who was born in Winchester, Va., 1835, and who died on September 19, 1900, at his country home on the Broad Road, Richmond, Va.

Dr. McGuire's character and power were not of the order of the self-made man, who triumphs in spite of circumstances, but of that finer, deeper kind that comes through heredity and careful training. He was descended directly from Thomas Mor McGuire, Lord of Fermanagh, Ireland, who was born in 1400, and was the son of Dr. Hugh Holmes McGuire, a prominent physician and surgeon in the South. From his father he received that careful preliminary training so essential to scientific development, and during his childhood lived in an atmosphere of intellectual progress. It was in the Winchester Medical College, of whom his father was one of the founders, that he began his medical studies, and it was from his father that he received his first instruction in surgery. He graduated in 1855 and then planned to continue his studies in Philadelphia at the University of Pennsylvania and the Jefferson Medical College; but ill health compelled him to relinquish this idea and he returned to Winchester where he served one year as professor of anatomy in the Medical College; but in 1858, feeling the need of greater clinical opportunities, he left the practice that he had started and returned to Philadelphia. There he not only carried on his advanced studies, but organized a large quiz-class for medical students that was largely attended by the Southern men. It was owing to this intimate relationship as an associate of these students that his power rose as a leader, and when at the time that John Brown's body was brought through Philadel-

phia, and the city was aroused to a pitch of great excitement, Dr. McGuire led three hundred students to Richmond where they felt that they could continue their studies under more favorable circumstances. There they were received with a stirring patriotic speech by Governor Henry A. Wise, and were matriculated without charge by the Medical College of Virginia. The city council even reimbursed the patriotic band to the extent of their traveling expenses; and

soon commissioned surgeon in the Virginia State forces, and then was appointed medical director of the Army of the Shenandoah, then under command of General T. J. Jackson.

It was during those years of the war that the young surgeon, not thirty years of age, did the brilliant work that recommended him to the personal friendship of his General, to whom he rendered the hero-worship of the youth, combined with the man of genius. In all battles his serv-

HUNTER HOLMES MCGUIRE, MD., LL.D.

Dr. McGuire received his degree of Doctor of Medicine a second time from the college.

It was during the following year, while Dr. McGuire was studying and teaching another quiz-class in New Orleans, that the secession of South Carolina occurred; and fired with that patriotic spirit which has characterized his whole life as a citizen, he hastened home and volunteered as a private in Company F, Second Virginia Regiment, and marched on April 1, 1861, from Winchester to Harper's Ferry; but he was

ices were reported with commendation, and his efforts to better methods of medical field service were supported by the commander, who recognized his ability and zeal. He organized the Reserve Corps Hospitals of the Confederacy, and perfected the ambulance corps; and from his experience evolved the daring and successful operations in abdominal surgery, which he presented after the war in a paper read before the American Medical Association. In this he advocated operative intervention in gun-shot wounds of the

abdomen. Prior to that time bullet-wounds in the intestines were inevitably fatal, and the United States Surgeon-General, in his report of the war between the States at that time, stated that there was not a well-authenticated case on record that recovered without an operation. This paper of Dr. McGuire's excited much attention and did much toward establishing the frequency of such operations which now save 67 per cent. of the lives. With Dr. Sims and Dr. Kinloch, Dr. McGuire shared the honor of being the pioneer in this branch of surgery, and his "Chapter on Gunshot Wounds" is one of his most noted surgical works.

It is not to be wondered at that the friendship of Jackson, Lee, Early and Elwell, whom he attended when sick or wounded, bound his sympathies to the Southern cause. His personal attendance on General Jackson, in whose Stonewall Brigade he was surgeon, the gift of a sword from his own hand, and his memory of the commander's last word's, "Let us cross over the river, and rest under the shade of the trees," as he ministered to him in his last moments, all served to arouse in him the strong patriotism, which after the War showed itself in his public-spirited efforts on behalf of the South. He kept alive by personal anecdote and stirring articles of reminiscence the tales of Southern heroism that form as integral a part of the nation's history as those of the triumphant North; and he took a prominent part in the investigations of the histories used in his State, and was instrumental in having those by Southern authors, and books containing the spirit of Southern literature used in the schools. All important topics concerning the advancement of the South were dear to him, and he gave his time and his advice freely to matters of public welfare.

After the war was over Dr. McGuire, who had finally been made the Medical Director of the Army of the Valley under Early until the surrender at Appomattox, returned to private life and began the practice of medicine in Richmond, practically a poor man. But the genius that had won him recognition even in his student days soon brought him practice. He was appointed to fill the chair of surgery in the Medical College of Virginia, as successor to Dr. Charles Bell Gibson. Popularity soon passed into fame. His successes were striking, his work original and careful, and his investigations those of a profound and critical thinker. His practice increased throughout the State and his advice was sought by his most distinguished contemporaries; and yet throughout the busiest days he found time for individual philanthropic work among the poor, and for personal sympathy and advice, especially to students and young men, whose friend he had been ever since his own student days.

In 1866 Dr. McGuire married Miss Mary Stuart of Staunton, Va., daughter of the Hon. Alex. H. H. Stuart, who was Secretary of the Interior under President Filmore, and had nine sons and daughters, all of whom, as well as their mother, survive him. Added to his family life and his professional clientèle was a large social circle of the most prominent people in Richmond and Virginia, among whom he was one of the most conspicuous figures. So widely known was he that when on the 19th of March of this year he was suddenly stricken with paralysis which rendered him speechless and helpless the profoundest regret was expressed throughout the city; and his death which followed six months of suffering was a source of sorrow to hosts of friends, and a loss to the professional men of the whole country.

Dr. McGuire's remarkable successes in lithotomy, lithotrity, and ovariotomy, and his works upon surgical subjects attracted the attention of surgeons in Europe as well as America. He was the friend and contemporary of such men as Sims, Campbell and Butty, and without doubt one of the greatest surgeons that the South has ever produced. All the honors that his State and country could give him were his. The degree of Doctor of Laws was conferred upon him in 1887 by the University of North Carolina, and in 1888 by the Jefferson Medical College of Philadelphia. He was president of the Richmond Academy of Medicine in 1869; of the Association of Medical Officers of the Army and Navy of the Confederate States in 1875 and of the Virginia Medical Society in 1880. But his truest honors were in the works in which he was engaged. As president, and professor of surgery of the University College of Medicine, and as surgeon-in-charge of St. Luke's Home for the Sick, he did work that will stand as a monument to him. Doubtless there is not a surgeon throughout the land but will pay his memory the tribute of a reverent regret and the appreciation of the brilliant far-reaching work of his full and eventful life.

DR. LEWIS A. SAYRE.

Dr. Lewis A. Sayre, whose name for fifty years has been a synonym for some of the most brilliant work in orthopedic surgery, died quietly at his home on September 21, 1900. For a year his health had been gradually failing and he had given up all active work; but no illness, other than the natural failing of old age, caused his death.

Dr. Sayre was born in 1820 in the town of Madison, N. J., and has been essentially a New York man, having pursued his medical studies at the College of Physicians and Surgeons, and gained his experience and made his discoveries in the clinics of this city.

Dr. Sayre had some amusing experiences while he was a medical student which he was fond of relating. The College of Physicians and Surgeons was then at 65 Crosby Street, near Spring. One day Dr. Post, one of the operating

surgeons, was about to cut off an Irishman's leg. Young Sayre had made complaints that the talks in connection with the operation were not explicit enough, so Dr. Post went into an elaborate exposition of flaps and circular flaps, the application of the tourniquet in amputations, the stoppage of hemorrhage by hot iron, and the various kinds of amputations.

The Irishman lay on the operating-table in full possession of his faculties, and as he listened to Dr. Post's discourse he grew whiter and whiter. Finally he jumped from the operating-table crying, "Get me me breeches, be gob; I'll die with me leg on!" And with that he was out of the room. The patient was a fireman who had been injured while going to a fire. Dr. Sayre found him several days later in a Watts Street dive, with his knee badly swollen. The young doctor had heard a lecture that morning on "tactus eruditus," so he performed an operation on the fireman's knee, opening the swelling and then binding up the wound. The rest is best told in Dr. Sayre's own words: "When my preceptor, Dr. Green, heard of what I had done he swore a blue streak. 'My God!' he said, 'you have opened the joint, something surgery abhors, a thing no surgeon ever did in the world.' But my patient got better. One day I had no lint to bind his wound with, so I used the tow stuffing sticking out of an old horsehair sofa. When I called again I found the wound open and free from pus, I could only conclude that the tow had caused the difference. I reasoned from this that tow, dipped in Peruvian balsam, would not only disinfect a wound, but would keep it free from pus. And this was the foundation of one of the most satisfactory successes I ever had in surgery. It was the means of introducing into the army the use of tarred hemp, or oakum, as a dressing for wounds. My fireman got well, and for twenty years sold apples from a stand at the corner of Broadway and Prince Street."

Lewis A. Sayre, M.D.

On reaching his degree in 1842 he was appointed prosector to Dr. Willard Parker, who was then professor of surgery in the College of Physicians and Surgeons, and held the position for ten years, when he became surgeon to Bellevue Hospital. Later he was appointed surgeon to the Charity Hospital on Blackwell's Island. It is interesting to note that Dr. Sayre gained his experience, as have done so many of New York's most famous men, in the city's institutions. In those days, as still, the service was severe, exacting and exhausting; but the experience was and is most varied and profitable. Thousands of the city's poor, the halt and the maimed, passed through Dr. Sayre's hands; and from them he learned the arts that have saved other thousands from deformities.

One of his patients, who had in youth been treated for Pott's disease by him, and had grown to be tall and strong, said that it was a not unusual sight to see the children who thronged his waiting-room run and throw their arms about him, begging to be made straight and well like others he had cured.

Dr. Sayre was tendered the position of resident physician of New York by Mayor Fernando Wood in 1860, despite the fact that he had bitterly opposed Mr. Wood's election. This position he accepted and continued to hold under Mayors Wood, Gunther, and Hoffman. During his incumbency New York was given a series of reports dealing with sanitary problems, such as the city had never known before. Dr. Sayre, who was known for his use of vigorous English, and for his progressive medical ideas, attacked first the lack of caution in preventing the spread of smallpox, and was untiring in his efforts to procure compulsory vaccination. The tenement-house evil, which had become apparent as early as 1865, was then taken up by him, and marked improvements resulted. His most important act at this period, however, was the detention of the cholera-infected ship "Atlanta" in the lower bay in 1865. Up to that time cholera was considered to be merely epidemic, and even the physicians of Boston in an official report the same year declared that "the disease is epidemic and cannot be restrained or controlled in its progress by quarantines or cordons of any kind."

To Dr. Sayre belongs the credit of having discovered that cholera is a contagious disease. Through his efforts all ships suspected of having cholera on board were quarantined, and the disease prevented from obtaining a foothold in New York. It was a long time before Dr. Sayre's theory was accepted in medical circles, and for many years New York was the only port where quarantine regulations in regard to cholera were enforced.

He performed the first successful operation for hip disease in this country in 1854; and then demonstrated his method before the medical colleges and societies. Lister, who was a delegate to the International Congress at Philadelphia in 1876, said that this demonstration alone was a sufficient reward for his voyage across the Atlantic. He again gave a series of demonstrations of his treatment of hip-joint and spinal disease as a delegate to the British Medical Association in 1877, before the University College Hospital, Guy's, St. Bartholomew's, St. Thomas', and the Royal Orthopedic Hospital in London. In 1894 at the International Medical Congress in Amsterdam, as well as at similar congresses in London, Copenhagen, and Washington, he read papers descriptive of his improvements and discoveries in the treatment of Pott's disease and various spinal complaints. Thus, he has disseminated the results of his patient, indefatigable work on these hitherto hopeless diseases, for the benefit of humanity, so that the surgeons of two continents have looked to him for their advance in these lines. His practical grasp of orthopedic and spinal surgery has shown itself in the invention of many instruments, in the adaptation of the plaster cast in the treatment of spinal diseases, as well as in many treatises on the subject. Dr. Sayre was at the time of his death a member of the most important medical societies and consulting physician to Bellevue Hospital, City Hospital, St. Elizabeth's Hospital and the Home for Incurables. He was, with his scientific progress and fame, distinctly a healer of the people, and no eulogy of print or press could be as strong as the heart-felt gratitude of the multitudes whom he has saved by his personal treatment, from lives of pain or deformity.

DR. ALFRED STILLE.

The oldest of the three noted physicians who have almost simultaneously finished their work was Dr. Alfred Stillé, who died at his home in Philadelphia, September 24, 1900, after an illness of six months. He was eighty-seven years of age, having been born in 1813. He belonged to an old Pennsylvania family of Swedish origin. In the days of William Penn the land of Olof Stillé, his ancestor, who had settled near Philadelphia in 1638, was known as Stillé's Land, and is now the only homestead of those early Swedish settlers that is known. With the prosperity of the city, the family grew in power, so that the accumulated energy and thrift and culture gave this son of the early century advantages which were sufficiently great to prepare him adequately for the wave of scientific investigation of the last fifty years.

Dr. Stillé was educated at the University of Pennsylvania, receiving his degree of M.D. in 1836, and was then elected resident physician at the Pennsylvania Hospital. Later he went abroad and continued his studies in Paris and other European capitals, thus laying the foundation of the scientific work which has made him famous.

Although Dr. Stillé was widely known in his

own city as a practising physician, both as attending physician to St. Joseph's for thirty years and as lecturer on pathology and the practice of medicine for the same length of time in the Pennsylvania Medical College, and the University of Pennsylvania, yet his fame throughout America and Europe rests chiefly on his scientific laboratory work. He was a careful, minute observer, a bold and patient experimenter, an indefatigable and brilliant writer. His lectures, his books, and the vast output of his laboratory work made his name widely known in America and Europe.

All the honors that Philadelphia and the medical societies to which he belonged could bestow upon Dr. Stillé were his. He was one of the secretaries of the convention out of which grew the American Medical Association, and for several years was a secretary of the latter body. He was president of the Philadelphia Pathological Society from 1850 to 1863, of the County Medical Society in 1862, of the American Medical Association in 1871, and of the Philadelphia College of Physicians in 1883, and a fellow of many other medical and learned societies. In 1876 an honorary degree of LL.D. was conferred upon him by the Pennsylvania College at Gettysburg.

Dr. Stillé's writings are standard works, and are masterly and scholarly productions. Among the works he contributed to literature are "Humboldt's Life and Character," "War as an Element of Civilization," "Othello and Desdemona;" while those on scientific subjects are voluminous and many. Perhaps the most prodigious work was the "National Dispensatory" (with John M. Maish), a work which has brought the science of pharmacy into definite relationship with that of medicine. His "Therapeutics and Materia Medica" is a well-known standard work, and his "Epidemic Meningitis" and "Epidemic Malignant Cholera" are works of original research that marked an epoch in the science of the nation.

Alfred Stille, M.D., LL.D.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, September 15, 1900.

THE SOUTH AFRICAN HOSPITAL COMMISSION—ARRIVAL OF THE COMMISSIONERS AT CAPE TOWN—PROGRESS OF THE INQUIRY—MR. KENDAL-FRANKS' REPLY TO MR. BURDETT-COUTTS' CHARGES—DEATH FROM SUFFOCATION BY ARTIFICIAL TEETH—THE OUTBREAK OF PLAGUE IN GLASGOW—DISPATCH OF DR. JENKINS OF THE NEW YORK BOARD OF HEALTH AND DR. THOMAS OF THE UNITED STATES MARINE HOSPITAL SERVICE—ELABORATE PRECAUTIONS IN THE PORTS OF THE UNITED KINGDOM.

The South African Hospital Commission arrived at Cape Town on August 24th and at once proceeded to take evidence. Prof. Dunlop of the Glasgow Royal Infirmary, who had given his services in field gratuitously, said that he was at the Wynberg Hospital for six months. There were plentiful supplies but excessive red tape. He thought that the Army Medical Department was not sufficiently advanced in modern surgery and that leave for the purposes of study should be given to Army doctors. The Commissioners inspected the Woodstock Hospital and examined 20 soldiers. They made practically no complaints except as to the lack of orderlies and doctors. Colonel Supple, of the Royal Army Medical Corps, said that 31,305 sick had been treated in the base hospitals at Cape Town and the mortality had been 1.15 per cent. The principal cause of death was pneumonia. Mr. Kendal-Franks of Dublin, one of the consulting surgeons to the forces, who was at Bloemfontein at the period to which Mr. Burdett-Coutts' charges apply and who took part in the march to Johannesburg and thence to Pretoria, has written a very long letter to the *Times* in which he characterizes Mr. Burdett-Coutts' charges as hysterical word-painting and says that, although he has seen unavoidable overcrowding, he has never seen in any hospital anything corresponding to the condition described by that gentleman. As to his insinuations that while the hospital tents were overcrowded many public buildings, which could have been used with advantage, were not, because they were used by staff officers; he points out that as the supply of nurses and doctors was below what was required, it was necessary to house the wounded so that the greatest advantage could be taken of the limited personnel. Each house which would accommodate, say six staff officers, could hardly take more than 16 or 18 patients and would require a couple of nurses and orderlies in addition to a cook and servants. Where were they to come from? Moreover, an enormous amount of extra work would be thrown on the already overworked medical officers. No lack of provision was made for the sick and wounded. The difficulty lay entirely in getting supplies up from the base, especially at Paardberg and on the march to Bloemfontein. The supreme importance of following up Cronje with the greatest rapidity and of hemming him in demanded that everything which would jeopardize the movement should be sacrificed even at the cost of leaving four-fifths of the ambulance wagons. To delay the march so as to provide a full complement of these would have entailed a prolongation of the war which would have cost far more lives and suffering than has been already produced. When Bloemfontein was occupied the army had to depend entirely for its supplies on what it could carry. The railway to the south was in many places in the enemies' hands. Before supplies could be brought up, the Boers had to be driven from these places and the line repaired. Did Mr. Burdett-Coutts realize that to supply sufficient food to the troops was the most humane precaution to prevent the spread of disease, that food for the healthy was more important than beds for the sick?

At Southsea a very peculiar fatality occurred. A gentleman was undressing on the beach preparatory to bathing. There was a very cold wind and the man in shivering with the cold swallowed his artificial teeth which choked him. When picked up he was dead.

The outbreak of plague in Glasgow has caused considerable alarm at all the ports of the United Kingdom. Places as distant as Cork in Ireland have taken the most elaborate precautions and are even preparing special isolation hospitals. All the vessels trading with Glasgow are on arrival inspected by the medical officers of health. Dr. Jenkins, Commissioner of Health of New York, who is taking a holiday in Europe, was stopped in London by cable from his Board and ordered to Glasgow to enquire into the character of the outbreak so that the New York sanitary authorities may decide upon the prudence of closing commercial intercourse with Great Britain. Dr. Thomas of the United States Marine Hospital Service has arrived in Glasgow to watch American ships on the Clyde. The very strictest quarantine is now observed at Gravesend. It appears that the outbreak began at the end of June. A woman died in a flat on a Sunday and was "waked." Her death was not made known to the authorities until the following Thursday when the body was in a state of advanced decomposition. Two women who attended the "wake" contracted plague and died. The Health Committee of Glasgow have decided to set apart the district from the center of which the plague cases were drawn as a well defined area to be placed under sanitary control. All the inhabitants and their dwellings will be under the observation of officials who can enter a house suspected even of having a nuisance. Street cleanliness will be enforced and the houses limewashed and otherwise disinfected. Two extra medical practitioners will be appointed for the specially defined area. An offer will be made to inocu-

late with antiplague serum all the inhabitants who are willing. All the hospital officials and others who come in contact with cases of plague or suspected cases will be inoculated. The outbreak has had a very serious effect on the shipping. The collector of customs has refused to issue clean bills of health to steamers outward bound from Glasgow. Foreign countries, such as Spain and Denmark, have begun to impose quarantine on Glasgow vessels.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Fiftieth Annual Meeting, Held at Wilkes-Barre, September 18, 19, and 20, 1900.

First Day—September 18th.

The society was called to order by the president, Dr. Geo. W. Guthrie of Wilkes-Barre, and addresses of welcome were delivered by Hon. F. M. Nichols, mayor of the city of Wilkes-Barre, and Dr. H. M. Neale, of Upper Lehigh, president of the Luzerne County Medical Society. The reports of the officers of the Society and of various committees were then read and the business of the meeting transacted.

Early Diagnosis and Treatment of Tuberculosis.—Dr. Charles Rea of Philadelphia considers that of the early symptoms the short, hacking cough, accompanied by a regular afternoon rise in temperature, is of great significance. Another important sign is the increased pulse-rate, with diminished arterial tension, while gastric disturbances are frequently observed and always to be carefully considered. In obscure cases the past history, hereditary taint, etc., are of much greater value in arriving at a diagnosis than the physical signs, which are often misleading. Of the newer aids the use of tuberculin is never free from the risk of lighting up a latent lesion, and the results of skiagraphy requires such skilled interpretation as to put the method out of the province of the general practitioner. The treatment consists in providing for an abundance of pure air and nitrogenous diet with change of climate, although the discomforts of travel often more than offset its advantages. Of remedial measures the intrapulmonary application of creosote by the nebulizer is most useful.

Antipneumonic Serum.—Dr. Edwin Rosenthal of Philadelphia said that no treatment was to be considered specific for all types of cases. In croupous pneumonia an approach to specific treatment seemed possible. Serum treatment must be begun early if it is to be of any service whatever. The side affected has been chosen for the injections. Twenty cc. of the serum is injected by means of an antitoxin syringe, the aperture being then closed by collodion. The dose can be repeated in from five to six hours. Temperature over 103° F. is an indication for the giving of the treatment. The use of the serum does not interfere with other treatment. (Dr. Rosenthal's paper will appear in full in the Medical News.)

Old-Time Treatment of Typhoid Fever.—By this Dr. W. H. Hartzell of Allentown means the methods in vogue prior to 1875. Three different stages of development may be noted, one up to 1860 when reliance was placed almost entirely on such drugs as digitalis, aconite, potassium iodide, silver nitrate, turpentine, etc., with an average mortality of 27 per cent.; another up to 1866, the period of incomplete antipyresis, with a death-rate of 16 per cent. and, finally, the time of systematic antipyresis lasting until 1875 and showing a mortality of 8 per cent. In the discussion Dr. A. A. Eshner of Philadelphia condemned the tendency of the rigid adherents of the Brand treatment to make hydrotherapy a stereotyped measure to be carried out without variation, regardless of the needs of the individual case. In every instance the procedure should be modified as the patient's condition seems to demand; it is better to get slight drops at short intervals than greater ones less frequently. Dr. Koenig of Pittsburgh advised the giving of large amounts of water, for in cases where the secretion of urine is free the prognosis is always good.

Lecturing Not Teaching.—Dr. T. D. Davis of Pittsburgh advocated a radical change in the present methods of medical instruction. Four years is ample time in which to acquire a medical education, in spite of the large percentage of failures at every State Board examination, but more real teaching should be done. The average college lecturer is very far from being a pedagog, and furthermore the disparities in the mental equipment of the students making up his audience are so great that no lecture in the first year can fully benefit all of them. During the first two years of college the work should all be done in recitations or quizzes and the minds of the students would then be sufficiently trained to hear lectures with profit.

The Human Temperaments.—Dr. J. C. Bateson of Scranton discussed the significance of the different psychological types in the practice of medicine. A true appreciation of the needs of the body can be arrived at only by a study of its relation to mental states and a knowledge of temperament as that of physiology.

Nervous and Electrical Energy.—Dr. J. Emmet O'Brien believes that nervous energy is the same as electrical energy and showed the relationship existing between the nervous mechanism and many forms of electrical machinery. Nerves are constructed like electric cables. They are insulated, distributed and arranged like fine electric conductors. Their purpose and use are the same as the purpose and use of electric conductors, namely, communication from point to point. They convey some form of force because: Electricity is always present when they act. Be-

cause it is the form of force that would do the work required. Because it is the form of force that would work with such construction. Because the terminal and central mechanisms connected with the nerves correspond to the terminal and central mechanisms connected with electric systems of communication and do similar work in sending, receiving, relaying, switching, transforming, accumulating, retarding, discharging, concentrating, distributing and translating impressions. Finally, because electricity is the only form of force that we know of that would do all the work required, with such construction of conductors and of terminal mechanisms. He concludes that nerve-force is electricity; that it is produced in the nervous system by chemical processes analogous to those which produce heat in the general tissues, *i. e.*, oxidation; and that it would advance knowledge of the nervous system and its functions to acknowledge this proposition, at least a working hypothesis.

Meningitis Complicating Pneumonia.—Dr. T. C. Ely of Philadelphia reported a case of recovery from this usually fatal combination. The patient was a boy of six years whose pneumonia was at first croupous and then became lobar. The meningeal symptoms set in on the twenty-third day and pneumococci, streptococci and staphylococci were found present.

Raynaud's Disease.—Dr. Judson Daland of Philadelphia presented the clinical history of a case of this disease. The patient was a woman of forty-three years who had had her hands and feet frozen twenty-one years previously and when seen was suffering in her fingers, toes and face. Under six months of massage and bathing her condition had improved somewhat. The urine had contained sugar for a period of three weeks with an excess of indican and an occasional trace of acetone but never any albumin.

The Diagnosis of Ectopic Gestation.—Dr. J. M. Baldy of Philadelphia reported a case for the purpose of calling attention to the absence of a sign usually considered diagnostic. The patient missed a menstruation in June and suffered from severe abdominal pains during July, August and September. At this time she was operated on and found to have a tubal pregnancy about three months old. At no time was there any vaginal or uterine bleeding, which shows that cases do exist in which the uterus makes no effort to throw off the decidua.

SECOND DAY—SEPTEMBER 19TH.

Fracture of the Spine.—This was the title of the address in surgery read by Dr. Walter Lathrop of Hazleton. In the mining regions such fractures are very common. The dorsolumbar region is most often involved. Paralysis below the seat of the injury with pains radiating or circumscribed are the most prominent symptoms. Laminectomy was recommended highly. Infection is the greatest danger. After-treatment of the oozing is very important. He described a number of patients operated on, all with partial success.

Symposium on Typhoid Fever.—"History and Statistics" was the title of a paper by Dr. J. M. Anders of Philadelphia read by Dr. Taylor of Wilkes-Barre in the absence of the writer. As late as the beginning of the present century typhoid and typhus were still undifferentiated and no distinction between the two was made, some abnormal forms of the disease being recognized, but considered simply as aberrant types. It was Louis of Paris who in 1829 first resolved the complex clinical picture into its two components and his American pupils, Gerhardt of Philadelphia and Jas. Jackson, Sr., of Boston, further developed the subject in this country. In England the old teaching prevailed until 1849 when Dr. Wm. Jenner advocated the recognition of typhoid as a separate entity, and a little later this view met with universal acceptance all over Europe. The most noteworthy feature of the disease as observed in recent years has been the persistence with which it attacks large bodies of men aggregated under poor sanitary conditions, as in military camps. In all the late wars it has been a prominent factor in raising the death-rate and the conditions of camp-life appear to be such that the outbreak of epidemics is inevitable. During the Spanish-American war it developed apparently spontaneously regardless of climate or locality and often without being preceded by dysentery. In the one encampment at Chickamauga over 9,000 cases came under treatment with a mortality of 7.13.

Etiology.—Dr. Chas. H. Miner of Wilkes-Barre described the biological and morphological characteristics of the typhoid bacillus and discussed the various means by which the infection is conveyed. Of these contaminated water is the most frequent, milk also often conveys the disease, usually through the washing of cans with impure water. Oysters fattened in fresh water may perform a like office and flies after crawling over the contents of latrines may infect food or convey the bacillus directly. Personal contact apparently does not carry danger with it, except under such conditions as prevail in military encampments where through the enforced close association and lack of conveniences the chances of infection are very much greater.

Complications and Sequelae.—Dr. H. A. Hare of Philadelphia drew attention to the fact that the typhoid of to-day is markedly different from that of former years. Text-book descriptions give the picture of a typical case, but in everyday practice one meets with very unusual forms. In its onset the disease is often acute rather than slow and constipation is commoner than diarrhea. The temperature-curve, instead of being the classic step-like ascent, often goes up with a rush and chills and fever simulating a malarial infection may be present. The cases in which the onset is sudden and overwhelming do not necessarily justify a bad prognosis, but are more often those in which active systemic antagonism

to the poison is going on and are likely to end in quick and uncomplicated recovery. In mild cases the invasion may be very gradual and the constitutional disturbance slight, so that errors in diagnosis frequently occur. The most common mistake is to take typhoid for gastroenteric fever which happens especially often in children who are not at all exempt, the common idea to the contrary notwithstanding. Instead of running its usual three- or four-week course, abortive forms are frequent in which convalescence begins in ten days or two weeks. All of these considerations show definitely that the disease is undergoing very decided alterations in its nature. In England the health reports of London, Manchester and other large cities show a constant decrease in the virulence of the disease and this same fact is very strikingly shown by the statistics of the last decade in Philadelphia and New York. Here a progressive diminution in morbidity and mortality was observed until the time of the Spanish-American war, when there was an enormous increase in frequency but an actual drop in the death-rate. This can mean only a very remarkable alteration in the nature of the disease, either a greatly decreased virulence or a rise in the resisting power of the organism to the typhoid toxin.

Treatment of Typhoid.—Dr. Alfred Stengel of Philadelphia said that we are forced to admit that we have no specific remedy at our command for the cure of typhoid. Hence our treatment has to be mainly directed toward supporting the patient and avoiding complications. In order to accomplish this it is of importance to supply a sufficiency of nourishment and in regard to feeding views are undergoing radical changes. Hydrotherapy intelligently applied is the most valuable form of treatment, but it is necessary to avoid its rigid application without regard to individual needs. Not every case needs it or is benefited by it and, especially in private practice, it has often to be omitted. Wherever the aversion of the patient is very great or the suffering produced by the tubbing is severe, it is better to do without it. The objections of friends, much shivering or nervousness and the hysterical and nervous outbreaks which sometimes occur also contraindicate it. Peritonitis and hemorrhage are complications that debar tubbing. The temperature of the water is to be regulated entirely by the way the patient stands the bath and the condition of his circulation before and after. Usually it is well to have it between 80° and 90° F. The tubs should come once in 3 hours if the temperature goes above 102.4° F.; if below this point but still above 101° F. sponging is indicated. The idea that if the temperature is below 102° F. it is not necessary to do anything in the way of hydrotherapy is fallacious, for, although the antipyresis produced is of undoubted value, many other advantages accrue from its use and some of the more mild and less troublesome forms should be resorted to. The length of time each bath is to be continued should be governed by the same considerations as the temperature and frequency and should be varied in each case according to individual conditions. Cardiac stimulants are always required, and of these the bath is the most potent and satisfactory. In addition alcohol may be required, but the prevalent tendency to the administration of large doses is to be strongly deprecated. Small doses, two drams, of brandy or whisky should be given, and if moderate quantities do not suffice no good is to be attained by the use of large amounts. Strychnine is a valuable adjuvant to the alcohol and may be advantageously used with it in alternate doses. In extreme cases camphor is without an equal and may be given hypodermatically in doses of one grain dissolved in fifteen minims of olive oil. Intestinal antisepsis limits the frequency of complications; silver nitrate may be given combined with opium if there is diarrhea and with belladonna or nux vomica if constipation is present.

Medical Laws of Pennsylvania.—Dr. W. H. Dudley of Easton read this paper. He said: The honest physician obeys the law; graduates in due and proper form; goes before the State Board of Medical Examiners, and either passes or fails to pass, and tries again; all of which he does at a considerable expenditure of time and cash. In looking back over the past few years, since our present medical law has been upon the statute books, there appears—at least in our section of the State—to be a growing disregard for it. For, although at first it did seem to have a certain amount of restraining influence upon the illegal doctor, that influence appears to be growing slowly, though nevertheless surely less and less. In the discussion Dr. Chas. McIntire of Easton said that the weak points of the present system lie in the facts that there are no official records of those entitled to practise medicine and that there is no official body to prosecute infringers.

Some Medico-Legal Cases.—Dr. T. M. T. McKennan of Pittsburgh divides the cases in which suits are brought into three classes: (1) Those in which there is severe primary injury, *e. g.*, fractures; (2) those in which an apparently slight injury is after some lapse of time followed by nervous symptoms, *i. e.*, traumatic neurasthenia; (3) those in which the injury is slight or there is none at all and the symptoms are exaggerated or entirely assumed. In illustration of the first class five case-histories were given in which recovery followed within two years after a pecuniary award for incurable injury had been made. Out of eleven cases of the second class a large part recovered or improved greatly inside of two years. In these cases the damage is mainly psychical and the element of actual trauma is but slight. The third class, that of malingerers, is easy to detect and recovers speedily after the pecuniary remedy. In the discussion Dr. Judson Daland of Philadelphia related a case of undoubted traumatic hysteria which persisted eight years after a judgment of $10,000

had been obtained. Dr. M. Price of Philadelphia urged the necessity of great care in giving medical testimony in cases of this sort in which the results often entirely refute the prognosis of the expert and bring the profession into disrepute. Dr. Weaver of Wilkes-Barre said that a neurosis is by no means the natural sequence of severe trauma, a study of 14,000 railroad employees who were seriously injured, but, of course, not able to claim damages, showed only eight instances of this disorder, while of the passengers injured on the same road over twenty per cent. were affected. Drs. Gibbons of Scranton, Davis of Pittsburgh, Pearce of Philadelphia and Bailey of Pittsburgh all considered the question of medical expert testimony and advised great caution on the part of the physician when summoned for this purpose. Dr. A. A. Eshner of Philadelphia said that the effect of suggestion might explain some of the cures of nervous troubles soon after an award of damages. Dr. McKennan closed the discussion by saying that the object of his paper was to show the existence of a definite class of cases to be grouped as traumatic neuroses and caused by psychical rather than physical trauma.

Remedies in Phthisis.—Dr. T. J. Mays of Philadelphia believes that pulmonary tuberculosis is essentially a disease of exhaustion which advances and recedes with the patient's strength, so that rest is of the greatest value in the treatment. The second factor is food, nutritious and easily digestible, given in small amounts at frequent intervals. The possibility of supplementing mouth-feeding by the rectal administration of food should not be forgotten. Fresh blood and suppositories of scraped beef are well absorbed by this route. Strychnine in small doses raises the tone of the nervous system and is of service. Hypodermatic injection of silver nitrate over the course of the vagus nerves in the neck stimulates these by counterirritation and affects the disease favorably. A few minims of cocaine solution are injected and then through the same syringe five minims of a two-and-a-half-per-cent. solution of silver nitrate are thrown in. Dr. S. Solis Cohen of Philadelphia in discussing the paper said that it is very advantageous to give the strychnine in doses of 1/120-1/150 every hour, as by this means the system is constantly under its influence. Red meats have the most food value; the stomach should be flushed with hot water an hour before meals. Open air night and day is to be advised wherever feasible, even for bedridden patients.

Treatment of Appendicitis.—Dr. M. Price of Philadelphia said that all cases of appendicitis are laws unto themselves and that generalizations as to what to do for appendicitis are futile. Pus can never be removed by medicines and pus cases invariably require operative treatment. Operations on patients who are practically moribund are mistakes. The great mortality lies in just this direction and comparisons between different operators are of little value, as a rule, because of the various points of view assumed by the different operators. After-treatment also has to be borne in mind in the interpretation of results. Dr. R. H. Gibbon of Scranton in discussion said that the curse of surgical treatment is the necessity for drainage, a condition often brought about by waiting too long. The first hint that pus is coming should determine immediate operation. Dr. G. G. Davis of Philadelphia said that there is no question that a great eagerness for operating was deplorable. In straight cases there can be no question as to the advisability of operation, but in cases of uncertain diagnosis great caution should be exercised. Ileocolitis is the greatest factor in mistaken diagnoses. Dr. J. M. Baldy of Philadelphia, commenting on the question of the removal of healthy appendices, said that there are numerous patients with persistent trouble who recover absolutely on removal of the appendix and yet not a trace of lesion has been found in the appendix. In such cases the results are more valuable than the record of pathologic alterations. Drainage is to be avoided. Nine cases out of ten requiring drainage develop pus. One should not search more than fifteen minutes for an appendix. Break up adhesions if necessary.

Puerperal Infection.—Dr. C. P. Noble of Philadelphia gave the address on obstetrics, taking as his main theme the prevention of puerperal sepsis. Early generalizations regarding methods of uterine disinfection were too broad. Conservative methods are now more in vogue. Better methods of treatment employed in the cities have brought about a much lowered mortality. There is too great mortality in general country practice and this is indicative of the fact that the rank and file of physicians are not practising antiseptic midwifery. The most important item in good obstetrical work is cleanliness of the hands. He cleans the external genitals, the hands, the hands of the nurse and the instruments, by the most rigorous methods. Intra-uterine douching is held to be a bad procedure. It fails to disinfect and interferes with natural methods of self-protection. Cæsarean section was also discussed by Dr. Noble. He said that the rights of the unborn child are to be taken more into consideration and since this operation had proven less and less fatal under good technic, it is to be more and more relied upon in approximate cases. European statistics are much better than ours, since here the operation is performed generally as a last resort. Careful mensuration of the woman's pelvis and of the child before labor would save many lives.

Prophylaxis in Gynecology.—This was also dwelt upon in the address. Careful attention should be paid to (1) development of the organs of patient; (2) to childbirth accidents; (3) to infections and (4) to tumors. In the first place many obscure neurotic patients have faultily developed generative organs. Infantile cervices are impor-

tant factors. Childbirth accidents, lacerations, etc., should be repaired at once. The most important infection is gonorrhea. Here instruction is an important item, as few of the laity realize the far-reaching importance of this apparently simple disease. In the matter of removal of tumors, conservative surgery is gaining ground yearly. Myomectomies are preferable to hysterectomies and the removal of healthy ovaries for the cure of nervous disease is a reprehensible procedure.

Appendicitis in Child.—Dr. Guthrie of Wilkes-Barre then showed a child of two years who had been operated on for appendicitis. The result was excellent.

Applied Anatomy Teaching.—Dr. G. G. Davis of Philadelphia advocated the more extensive teaching of applied anatomy in our medical schools. Descriptive anatomy, while being the foundation of all medical works, is too much taught and its practical applications in surgery neglected. The tendencies of modern teaching are to practical methods. The teaching of anatomy should keep abreast of the times. Dr. Beattie of Philadelphia heartily endorsed the ideas of Dr. Davis and gave his experiences with the applicants for State Board examinations. Medical reciprocity will become an established fact as soon as there is a systematization of the courses in the curricula.

Surgery of Gall-Bladder.—Dr. O. C. Gaub of Pittsburgh read a paper on this subject, considering only those cases in which there is patency of the hepatic and common ducts. He believes in the infectious origin of gall-stones in which connection cholelithiasis following typhoid is an interesting sequence. Hepatic colic is a result, not of the passage of a gall-stone, but of the cholecystitis. One attack of colic disposes to others. He advocated the operation of cholecystectomy as the best, because the diseased organ is removed, convalescence is shorter and there is not any greater mortality. The indications for operation are hydrops, empyema, chronic inflammation and carcinoma.

Removable Buried Suture.—Dr. Evan O'Neil Kane of Kane then described an ingenious method of using a buried deep silver suture which can be readily removed.

Tuberculosis of Bladder.—Dr. F. P. Ball said that, although this disease is comparatively rare, its early recognition is so important that any differential diagnostic features are of interest. Pain in the rectum and in the middle of the penis was present in a case reported. There also was pain when the bladder was full rather than when it was empty. Dr. Noble in discussion said that both the diagnosis and treatment of this condition are simpler in women than in men, since cystoscopy is so much easier. Patients can be cured when the disease is not too extensive by the local application of silver nitrate. This is best applied through Kelly's cystoscope, thorough canterization being followed by after-washing with salt solution. Vesicovaginal fistulæ, with steady applications of silver and thorough drainage, also cure at times. Excision is to be recommended in severe grades of the disease. Dr. Baldy said that the finding of the bacillus is necessary to confirm the diagnosis; without such confirmation he would hesitate to say that he had cured a tuberculous ulcer of the bladder by any other method than that of entire excision. The early use of the cystoscope should be more extensively practised.

Silver Nitrate in Dermatology.—Dr. J. C. Dunn of Pittsburgh has found that silver nitrate in solution, grs. v-℥i, and locally applied is an excellent stimulant in eczema, all forms of which, as well as psoriasis, yielding to this application. It is well to apply chrysarobin and salicylic acid to one side of the body and the silver nitrate to the other and after a week let the patient decide which he likes best and desires to continue. Other diseases cured by this application are erythema, acne, herpes zoster, impetigo, lichen planus, and apparently a beginning epithelioma. In inflammatory or parasitic skin diseases no other drug is so good as silver nitrate, which seems to have an alterative effect on the nutrition of the skin.

Constipation or Obstipation.—Dr. William M. Beach of Pittsburgh under this heading describes the operation of valvotomy which is nearly always curative in its effect. Either one or more of the rectal valves may be removed, the operation being done through a four-inch protoscope. The valve is first sprayed with cocaine solution and then a solution of suprarenal extract is applied. It is then put on the stretch by the insertion of a tenaculum at either end and the desired part removed with a small curved knife. Gunshot sutures are applied and a firm tampon inserted. The dangers are from the bleeding, which is usually very free but may be greatly diminished by the use of the adrenal extract, and from peritonitis following a chance cut through the rectal wall into the peritoneal cavity.

Roentgen Method.—Dr. Chas. Leonard of Philadelphia considers skiagraphy one of the most valuable adjuncts to the ordinary means of diagnosis, but skill is needed in order to profit fully by it or even to interpret accurately its meanings. The Röntgen-ray operator requires the broadest sort of knowledge; he must be a thorough anatomist, a skilful clinician, and, in order to master the difficult technic, must have had wide electrical and mechanical training. The findings of the X-rays are absolutely accurate because founded on physical laws, and errors that arise are due solely to faulty interpretation. In general the surgical applicability of the rays lies in the location of foreign bodies in the tissues, the detection and control of fractures, in determining the nature and extent of orthopedic conditions, in diagnosticating new growths, and, finally, in differentiating calculi in the uropoietic system. In the trunk and head difficulties still

exist and although fractures may be detected it is not always possible to exclude them. It is especially in the case of compound fractures that the rays are of practical value, for extensive exploration of the wound may be dispensed with and the patient be spared pain and the vitality of the tissues not further jeopardized. In cases of suspected renal, ureteral or vesical calculus an absolute diagnosis may be made and the stone positively detected or excluded. In 90 cases subjected to this test a stone was present in only 20; of these the smallest weighed 9/10 of a grain and the largest one was two inches in length. In the discussion Dr. Culp asked whether small calculi, especially those of uric acid, could not easily be overlooked. Dr. Leonard said that in his experience there was no such risk and referred to the smaller stone above mentioned which was a uric acid calculus. In doing work on the kidneys it is essential to use a low-tension tube.

Paralysis Agitans Without Tremor.—Dr. A. A. Eshner of Philadelphia called attention to the fact that many diseases receive their designation from symptoms supposed to be characteristic but which in reality are not constant. Thus we sometimes see typhoid fever without either the typhoid state or fever, smallpox without the exanthem, exophthalmic goiter without protrusion of the eye balls or tumor of the thyroid and paralysis agitans without the tremor or the typical pill-rolling, pen-holding or wool-spinning movements. In such cases the diagnosis must rest on other signs, *viz.*, the expressionless face, the subjective feeling of heat, sweating, restlessness necessitating frequent change of posture, the festinating gait and absence of mental symptoms other than the loss of memory sometimes observed.

Tuberculous Adenitis.—Dr. L. J. Hammond of Philadelphia divides the treatment of tuberculous glands into two forms, constitutional and surgical. Under the first heading fresh air, sunlight and exercise, combined with abundance of pure food, are of the greatest importance. Of the drugs to be used the most suitable are strychnine, quinine, iron, potassium salts and cod-liver oil, the latter being best applied by inunction. Surgically the disease is to be treated in three stages, the glands, the abscess and the sinus. The glands, if small and in the early stages, may yield to medical treatment and inunction with iodoform or the injection of a twenty-five-per-cent. solution of glycerole of iodoform. If this is not successful, or if there is a tendency to softening, they should be removed by dissection, avoiding breaking the capsule if possible. If abscess-formation has already taken place incise and evacuate and then irrigate with 1/1000 bichloride solution. The incision should be a free one and thorough curettage of the granulation-tissue done. Primary union may sometimes be secured by omitting packing and bringing the parts together at once and applying an immobilizing dressing. Sinuses should be excised and their edges curetted.

Dr. J. A. Ehler of Lancaster exhibited and presented to the Society a portrait of Dr. J. L. Atlee, who in 1848 did the first ovariotomy performed in the State, together with a pamphlet by the operator describing the operation.

Third Day—September 20th.

Hygiene.—The address in hygiene was delivered by Dr. Joseph T. Rothrock of West Chester, State Commissioner in Forestry. He said that it was not an impossibility for the State supply of water to fail, and he insisted on the important relations existing between forests and water supplies. With reference to the question of tuberculosis he pointed out the inconsistency of not permitting tuberculous cattle to be imported into the State and yet no provisions were made against the entrance of tuberculous human beings. The State forest reservations were spoken of as ideal places for the tuberculous and he advocated them as proper resorts for State hospitals.

Bacterial Purification of Sewage.—Dr. D. H. Bergey of Philadelphia described briefly the two systems of sewage-disposal which at present seem to give most satisfactory results, *viz.*, the separate-tank system and the contact system. The technical difficulties in the way of maintaining sand filter-beds in satisfactory operation are so great that other means had to be looked for and these two seem to answer the requirements. In the first the sewage is kept for sometime in a large air-tight tank where the liquefying bacteria dispose of a large amount of the organic matter and from here it is passed onto filter-beds in which the nitrifying bacteria complete the work. In the contact system two open tanks are employed each containing from three to six feet of coke or clay. After being kept in the first of these for from one to two hours the sewage is discharged into the second from which the effluent emerges with seventy-seven to eighty-three per cent. of its organic matter converted. Either of these two processes is more efficient and practical than any filtration method. Dr. R. H. Gibbons of Scranton said that Pittston had suffered greatly from epidemics of typhoid until its water supply was changed and no longer contaminated by the sewage of Scranton. Dr. G. W. Guthrie of Wilkes-Barre cited Atlantic City, N. J., as having admirable sanitary arrangements inasmuch as the sewage is disposed of by sand contact-beds two miles inland and the water supply is derived largely from artesian wells. In closing the discussion Dr. Bergey said that the installation at Atlantic City was not a true contact system and not wholly satisfactory.

Higher Physiology.—Dr. E. N. Ritter of Williamsport made a plea for the same care and judgment in breeding and bringing up members of the human race as is exercised in the management of cultivated plants and the domestic animals. Vast numbers of persons who are physically and mentally unfit enter the married

state, conception takes place under adverse conditions, the hygiene of pregnancy is not observed and the result is that prisons and hospitals are full of individuals bodily and morally tainted from birth. Maternal impressions are of the highest importance in laying the foundation for a fine mental constitution and the best time to mold character is before birth. Another important problem consists in the sexual education of the young which, if properly done, never leads to harm. Dr. Bates congratulated the speaker on her bravery in taking up this topic and referred to recent attempts in Ohio to make medical examination of the contracting parties a legal preliminary to the granting of the marriage license. Dr. Massey considered that the education of women in regard to the functions of maternity was too much neglected and that it was especially the woman physician who could remedy the deficiency. Women should be warned of the dangers of marrying unexamined men, things tending to produce dangerous maternal impressions, such as some gaudy advertisements and posters should be removed from the streets and young people about to marry should be fully instructed as to the responsibilities involved in the bringing forth of children. Dr. Myers of Huntington cited the case of a couple in New York from whom a race of 200 criminals had sprung. In prisons and penitentiaries the inmates with acquired criminal tendencies should be kept separate from congenital malefactors and the latter castrated. Further comments were made by Drs. Gibbons and Koenig followed by Dr. Bishop who said that the idea of maternal impressions influencing the character of the fetus was a fallacy and that prematrimonial examination was degrading and not to be tolerated.

Sanitary Milk for Children.—Dr. B. H. Detwiler of Williamsport reported on an experiment he is conducting with the view of producing a sanitary milk for children. The milk of cows periodically undergoing sexual excitement is irritating and often produces intestinal derangements in infants. It has been proposed by French authors to obtain a milk not subject to changes of this sort by spaying the cows, which continue to give milk for five or six years and then may be killed for beef. In the experiment made by the reader two cows had been spayed by the vaginal route a year ago with apparently satisfactory results, as far as milk production was concerned, although a longer time must elapse before definite conclusions can be drawn. Dr. D. H. Bergey of Philadelphia said that the chief danger in infants' milk is in the bacteria it contained, streptococci being especially apt to produce gastrointestinal disorders and that it would be interesting to see whether the operation proposed would affect this factor also or not. Dr. Alfred Stengel of Philadelphia said that improvement in the quality of the milk is to be reached only by changes in the existing dairy conditions. The milk richest in cream is not necessarily the best for infant feeding, for example, the Channel-island cow's milk is greatly valued for its high percentage of butter fat but is quite unsuitable for the rearing of babies. Dr. Detwiler closed the discussion by saying that certain of the inmates of the Danville Asylum who were fed almost exclusively on milk were subject to epidemics of digestive disorders which apparently could be due only to changes in the composition of the milk.

Cataphoric Treatment of Cancer.—Dr. G. B. Massey of Philadelphia stated that the object of this treatment was to deposit mercury in the nascent state in the growth and so to produce an area of complete necrosis and a surrounding zone of sterilization. This is accomplished by the use of a hollow gold positive electrode through which metallic mercury may be forced into the growth, the negative pole being a lead plate applied to the patient's back. Since 1893 he has treated 37 cases by this method with 10 cures, 3 doubtful results and 24 failures. Dr. G. E. Shoemaker of Philadelphia said that in this as in all methods intended to act by cauterization distant unrecognized foci could not be reached, and that there was no reason to suppose that diseased tissue could be differentiated from healthy by the process. Dr. Massey replied that the effect produced is not only a cauterization but that the mercury infiltrated the surrounding parts also.

Nausea and Vomiting of Pregnancy.—Dr. John M. Batten of Downingtown in his paper brought out the intimate interrelationship between heart, stomach and uterus. During pregnancy the pressure of the growing child stimulates the uterus and in turn the other organs are sympathetically deranged. The one cure for obstinate vomiting under these conditions lies in constant feeding, whenever awake during the night food should be taken, a substantial meal should be made before rising and three others should follow during the day.

Paroxysmal Delirium.—Dr. W. C. Hollopeter of Philadelphia called attention to the growing belief in autointoxication as the etiological factor in many pathological states and cited three cases of sudden cerebral disturbance apparently due to the absorption of septic products from the intestine. The patients were all children and after a longer or shorter duration of the mental symptoms, fever and prostration promptly recovered under copious colonic flushing and intestinal disinfection. Dr. Judson Daland of Philadelphia observed that the presence of large amounts of indican and acetone in the urine points strongly to this form of poisoning and that no doubt other similar substances are to be found, although we do not as yet possess the reactions to demonstrate their presence. Dr. Savery Pearce described a somewhat similar case in which mild delirium slowly developing with low fever in a child promptly responded to high injections and the wet pack.

Nephritis in Gynecological Practice.—Dr. George E. Shoemaker reviewed the predisposing causes to this affection especially associated with disease of the female pelvic viscera. The general conditions of pregnancy favor the development of kidney trouble, for example, the sagging of the anterior vaginal wall induces a secondary sacculation of the bladder leading to difficulty in emptying it and decomposition of the urine which explains many cases of nephritis. Gonorrhea, sitting on the cold or damp ground, catheter cystitis, chronic pelvic inflammations, the wearing of thin-soled shoes and unsuitable underwear in winter, all may induce the disease. Ether anesthesia may light up a latent nephritis and atypical uremic symptoms after operation may simulate sepsis. If a major operation is imperatively called for the presence of nephritis does not contraindicate its performance, but greater caution and watchfulness are necessary.

Chronic Myocarditis.—Dr. John H. Musser of Philadelphia stated that the importance of this disease is rather greater than generally supposed and that valvular disease with a healthy heart muscle is not as serious as it is often considered. The symptoms of myocarditis are usually blended with those of concomitant lesions and the affection depends to a large extent on the same etiological moments as these. In general it may be divided into that secondary to pericarditis, following valvular disease, toxic myocarditis and fibrinous myocarditis or coronary-artery disease. This latter form usually accompanies general senility with a universal dulling of the sensibilities so that many of the typical symptoms are absent. In middle life, however, pain and dyspnea together with the Stokes-Adams syndrome of dyspnea, coma and slow pulse are frequently observed. Of the objective signs the peculiar sallow pallor with a prematurely old and wrinkled facies is very typical. On physical examination degenerated arteries and high tension are commonly found while in addition to the signs peculiar to myocarditis there may be those of either dilation or hypertrophy. Reduplication of the first sound is frequent and may be limited to the right or the left heart or be audible all over. Clinically the disease may occur either alone or with pulmonary, cardiac, cerebral or renal symptoms predominating.

Ovarian Hydrocele.—Dr. Reed Burns of Scranton described three cases of this condition which seemed to be due to an unusually deep ovarian fossa, retroflexion of the uterus and local plastic peritonitis.

Do We Resort Too Frequently to Surgical Operations?—Dr. R. H. Gibbons of Scranton considered some of the many conditions where operative treatment gave the only hope for the patient and concluded that the reproach that the surgeon was overzealous with the scalpel was not well founded.

Ophthalmology.—The annual address was delivered by Dr. Charles McIntire of Easton who drew a parallel between the advance of our modern social conditions and the growth of ophthalmological nomenclature. It is surprising how large a portion of the oculist's technical vocabulary consists of words beginning with *a* and in most instances it is the prefix of negation, the alpha privative. At the beginning of the century it was not so, amaurosis was the only word of this class and in this the initial letter is not a prefix, special knowledge was still in its infancy and instruments of precision were lacking; to an age without the ophthalmoscope things seemed simple and superficial because the ability to look below the surface was wanting. And in a similar way the conditions of life were less complex and existence seemed simpler because its possibilities were still in an undeveloped stage. But little by little the understanding broadened, the old-fashioned amaurosis became the *a*-metropia of Donders and the alpha privative began to make itself felt. And now asthenopia has come and with it countless other terms each negativing a function and typifying the conditions of our modern life where the alpha privative is constantly asserting itself, and telling of weakened organs and vital processes improperly performed. In this way the science of life and the science of the eye have gone hand in hand for a century, and as we look to the future we can only wonder what changes will come during the next hundred years and whether at their end the alpha privative will still be in the ascendant.

Electro-Magnet in Eye Surgery.—Dr. E. B. Heckel of Pittsburgh described a special form of electro-magnet possessing many advantages over those in common use. Among there are cheapness, lightness, ease of manipulation, a core of soft steel which requires an appreciable length of time to acquire its full power when the current is turned on, so that the pull exerted is less sudden, the ease with which the core may be removed for sterilization and the special form of tapering point which carries a maximum of magnetic force to the very end. In the use of electro-magnets in removing foreign bodies from perforating wounds of the eyeball it is important not to turn on the current until the point is in position and all adjustments have been made. Additional incisions into the chambers are not justifiable. Dr. J. E. Willets of Pittsburgh discussed the instrument and stated that it fulfilled every requirement perfectly. While it is not as powerful as are some that have been recommended great force is a danger rather than an advantage and the Heckel magnet is entirely satisfactory. Dr. L. H. Taylor of Wilkes-Barre described a case of foreign body imbedded in the retina which was sent to Dr. Hermann Knapp for treatment. The very powerful Haub magnet was used in this case, but the object was not dislodged. The next day it had disappeared from the ophthalmoscopic field and the patient was discharged under the supposition that it had slipped entirely through the posterior wall and

was out of harm's way. The event has apparently justified this view for the patient has almost entirely recovered the sight of the injured eye and experiences no discomfort.

Oculist and Optician; Physician and Public.—Dr. P. J. Kress stated that the public should be educated to recognize the difference between the oculist and the optician, which latter is usually little better than a quack. The proper fitting of glasses, like every other special branch of medical knowledge, requires a broad general training and cannot be properly performed by one bred only to the selling of spectacle-frames.

Dr. Charles H. Miner of Wilkes-Barre presented two cases of leukemia and pseudo-leukemia, showing the typical features of these diseases.

Surgery of Ear.—Dr. J. E. Willetts of Pittsburgh described an operation which consisted in removal of the tympanum and the ossicles with opening up of the mastoid cells if needed. If the discharge at any time seems to be greater than is accounted for by the disease of the middle ear, involvement of the mastoid should be suspected.

Climatology of Neurasthenia.—Dr. F. Savery Pearce of Philadelphia made a plea for greater exactitude in our knowledge of meteorological therapeutics and more definiteness in our directions to patients whom we are sending away. Neurasthenia is a malnutritional malady of the central nervous system and especially amenable to climatological treatment during convalescence. Damp, low, treeless regions are unsuitable, as are also high altitudes where the pressure is low. Altitudes below 2000 feet are usually to be recommended; whether sea air or mountain air depends largely on conditions of pressure, flora and idiosyncrasy. Localities where storms prevail are to be avoided. On this continent Nova Scotia, New Brunswick, Muskoka and the Ontario regions are to be especially recommended. Sea voyages make an excellent prelude to the longer stay in the selected locality.

Removal of Third Tonsil.—Dr. L. J. Lautenbach of Philadelphia described the operation as performed by him without anesthesia or instruments. The use of chloroform or ether in these cases is especially hazardous on account of the depraved general condition of the patients and many published and unpublished deaths have occurred from this cause. Instrumental operation no matter in what form done is always incomplete because it is impossible to feel whether all the tissue has been removed and therefore recurrence is common. Dr. Lautenbach's method is to curette the postnasal space with the fingernail, the artificial fingernail devised by him being employed if the growths are very resistant. Performed in this way the operation is quick, lasting only from ten to twenty seconds, is safe, easy, thorough, is done in one sitting, requires no instruments, causes no pain, shock or fright, and is entirely free from risk.

Animal Organisms in the Ear.—Dr. F. R. Packard of Philadelphia presented a résumé of the cases in the literature in which living animal organisms were removed from the external ear.

Typhoid.—Dr. James Fulton of New London read this paper, which considered in detail many interesting features of this disease.

Esophageal Stricture.—Dr. Charles H. Frazier's patient presented an impassible cicatricial stricture of the lower esophagus for which a gastrotomy with attempt at retrograde dilatation seemed the only remedy. As a last resort a series of silver balls, from two to seven millimeters in diameter and perforated to receive a thread, was procured. The patient was given the smallest of these fastened to a silk thread and directed to swallow it. After a number of hours it passed the stricture, was withdrawn and a larger size introduced. In this way the stenosis was gradually dilated till bougies could be introduced and a cure finally effected by dilatation.

REVIEWS.

Transactions of the American Microscopical Society. Vol. XXI. Edited by the Secretary, Twenty-second Annual Meeting. Lincoln, Neb., 1900.

The *renaissance* of the American Microscopical Society is evidenced by this as well as by the volumes of Transactions of the past few years. From a mildly inefficient collection of amateur microscopists, publishing a few scattering contributions to popular science, the society has grown to represent an important body of scientific workers in the biological sciences and the Transactions offer monographs of actual merit. Interesting the Transactions always have been; they now present something more permanently useful to microscopical science. Of the papers more particularly bearing on medical science those by the President, Dr. W. Krauss, on "Medico-Legal Aspects of Trauma and Diseased Cerebral Arteries;" "Diabetic Blood Reactions," by V. A. Latham; "Chlamydomonas and its Effects on Water-Supplies," by G. C. Whipple; "Eyes of the Blind Vertebrates of North America and Some Laboratory Apparatus," by S. H. Gage, are the more interesting. Botanical and zoological contributions are numerous.

The Cell in Development and Inheritance. By Edmund B. Wilson, Ph.D., Professor of Zoology, Columbia University. Second Edition Revised and Enlarged. The Macmillan Company: New York and London. $3.50.

We have had occasion in a former issue of the Medical News to express the opinion that we believe this work to be the finest on its subject that has ever appeared. We do not except the works of Hertwig nor of Henneguey.

The present edition has been more than re-

vised. A careful reading shows that it has been rewritten and in its new form lays even greater claim to the high place accorded it. While for the general medical practitioner this work will be found to contain little that is of direct practical benefit, either in the diagnosis of disease or in the treatment of the same, for those inclined to ponder on the problems afforded by the study of the physiology and pathology of function no better guide can be found for a fundamental knowledge of the questions of cell-life. The careful and systematic mode of presentation argues well for the literary as well as technical skill of the author. He grasps the sense of perspective, subordinating many details to the general plan.

For those who would keep abreast of the advances in cell-biology the work is indispensable, and for those who take but a quasi-interest in the problems here considered we would predict an intellectual treat.

A Manual of Surgical Treatment. By W. Watson Cheyne, M.B., F.R.C.S., Professor of Surgery in King's College, London, Surgeon to King's College Hospital, etc., and F. F. Burghard, M.D., and M.S. (Lond.), F.R.C.S., Teacher of Practical Surgery in King's College, Surgeon to King's College Hospital, etc. Volume III. Philadelphia and New York: Lea Brothers & Co., 1900.

The third volume of this eminently practical work deals with the treatment of the surgical diseases of the bones in its first part, and with amputations in its second. The authors, for considerations of space, have left the treatment of orthopedic diseases for the next volume. Indeed, they have decided to produce the work in seven volumes instead of six, as originally intended.

The authors fail to give consideration to the ambulatory treatment of fractures of the leg, a subject of increasing importance at the present moment. In other respects, their chapters on this phase of surgery is admirable and includes the constant injunction to verify the diagnosis and the correctness of position by the Roentgen rays. They correctly consider osteomyelitis and periostitis separately, although at variance with some pathologists who aver that the diseases are identical but represent different stages. The consideration given to tumors of the bones is terse, but is consistent with the intention of the authors to limit pathologic data to essential elements.

In the second division of the volume there is a full, modern paper on amputations from which is eliminated all unnecessary and burdensome material. It reflects purely the experience of the authors. As usual, the after-treatment of the patient is fully considered. The illustrations are copious, are especially well drawn, and are mostly original. This volume, it appears to us, must prove particularly valuable to the general practitioner as well as to the surgical specialist.

Simon's Clinical Diagnosis. A Manual of Clinical Diagnosis by Microscopical and Chemical Methods. For Students, Hospital Physicians and Practitioners. By Charles E. Simon, M.D., late Assistant Resident Physician Johns Hopkins Hospital, Baltimore. Pp. 563. With 136 Engravings and 18 Full-Page Colored Plates. Cloth, $3.50 net. Lea Brothers & Co., Philadelphia and New York.

It is a very encouraging sign of progress in scientific medicine in America for a text-book on clinical diagnosis to reach a third edition within four years. Time was when only books on treatment sold into more than two editions in less than five years. As a rule, publishers hesitate about taking text-books on diagnosis for publication at all. Dr. Simon's Manual is in its third edition and there seems no reason to think its popularity will wane. Not all text-books on diagnosis published in the last few years have had a like success, however, and it is a lesson in medical book-making to note the reasons why this manual has sold so well. The qualities that have given it its popularity are, first, its utter practicalness. Nothing is introduced for the sake of erudition, nor merely because it has been a subject of more or less limited discussion in certain medical circles. Secondly, its completeness. Nothing is omitted that the practitioner might find of assistance in eventually perfecting his diagnosis. The discussion of the subject of phosphates in the urine is a typical example of this completeness. This rather indefinite topic is handled in a way to give as clear ideas as possible to the practising physician in the present state of our knowledge of the subject. A third reason for the wide sale of the book is the beauty and significance of its illustrations. The colored plates of the blood are very excellent reproductions of well-prepared specimens. The presentation of the whole subject of the blood is such as might be expected from one of the Johns Hopkins school and more cannot be said. As might be anticipated the illustrations on malaria are well calculated to give correct notions for microscopic diagnosis of phases of malaria, even to those who have not had an opportunity to examine actual specimens.

The two plates on phenyl-glucosazon crystals obtained from diabetic urine and that on the color-reactions in different urines after the addition of the nitric-acid test are really very perfect specimens of the printer's art. It is a pleasure to chronicle the fact that books like this are being written and made (as the making has added greatly to its value) for the medical students and the practising profession in America. The author in his preface says he thinks that most of the volumes of preceding editions were taken by practitioners. This is an inspiring sign that the younger generation of practitioners is careful to let slip no opportunity to keep abreast of the advance in scientific medicine where progress touches practice.

ORIGINAL ARTICLES.

INTERNAL SECRETION OF THE OVARY.

BY ARTHUR W. JOHNSTONE, M.D.,

OF CINCINNATI, OHIO.

RETAINED excretions are the causes of nearly all nervous conditions, whether at the menopause or during menstrual life. This is a commonplace statement to many of you, and those who have been general practitioners have utilized it in the handling of both their male and female patients; but some have lost sight of it in the recent furor that has been raised over the "internal secretion of the ovary."

Under ordinary circumstances this paper would be entirely out of place, but when the President of the British Gynecological Society, in his last presidential address, 1900, assumes that the ovary has an internal secretion, it is incumbent on those who do not believe it to bring forward the proofs of their faith.

There is not an iota of proof that the ovary has any other function than the manufacture of eggs. For fifty years we have known that the ovary is active during intra-uterine life and that it begins to ripen Graafian follicles at the sixth month of gestation; that this continues rather rapidly until after birth; that during infancy the Graafian follicles still ripen occasionally, but not as rapidly as before birth, and persist in the same ratio up to puberty. At puberty the follicles ripen more rapidly, at least five or six a year, but at no time do they amount to as many as the number of menstruations in the year. This rate continues during the whole of the child-bearing period. During and after the menopause the Graafian follicles still continue to ripen. Of all the ovaries past the menopause that I have removed, I have never found one that did not possess a small number of Graafian follicles in an immature state, and I have frequently found those that have recently ruptured.

The ovary is in no sense a gland. Its epithelium is arranged for the purpose of being cast out and lost, and is not placed so that its secretions, if it has any, could be absorbed either by ducts or blood-vessels. The adherents to the internal-secretion theory claim that it is like the suprarenal, the thymus or the thyroid gland. This I can state positively is not correct. Years ago I made careful studies of these organs. The thymus gland is nothing but the large lymphatic gland which does the work of the lymph structures during intra-uterine life. Its lymph vessels are just the same as those of the axilla or groin. The thyroid gland and suprarenal capsule have no lymphatics that amount to much, but a very rich supply of blood-vessels so arranged that each epithelial cell is closely approximated to a venous radical, thus providing for a rapid absorption of whatever secretion its cells may make. As far as we know these cells are never entirely removed except by a low form of colloid degeneration, which colloid material is readily absorbed by the blood-vessels close to it.

But the ovary has a true duct through which its epithelium when cast out passes off *en masse* to the outer world. In the erect animals the Fallopian tube has great mobility and can attach itself to any particular part of the ovary, but in the dog and wolf the fimbriæ are united to each other and embrace the whole of the ovary and are attached to its base, so that there is no communication between the tube and the peritoneal cavity. This difference is for the reason that the eggs in the dog are ripened in groups, and as the tube has more than one Graafian follicle to deal with at a time, it must surround the whole of the ovary so as to catch everything that comes from it, thus providing a sewer down which everything must pass which comes out of the ovary. Therefore the analogies about which so much has been written do not hold good anatomically. Had the propounder of this dogma made any allowance for menstruation as a separate entity, free from the domination of the ovary, he certainly would have paused before announcing any such doctrine.

If it is a lack of an internal secretion that causes the nervous disturbances of the menopause, why is it that the little girl does not have them? But more unanswerable than this, why is it that a delayed menstruation in a child-bearing woman will produce identically the same symptoms as those of the menopause? This is apparent in all of our every-day work. Let me relate a striking instance.

Last autumn I had in my private hospital a splendidly developed woman of thirty-two, from whom I had removed the whole uterus and both ovaries for a degenerated fibroid. Of course, she had all the hot and cold flashes and nervous disturbances that usually go with such conditions. In the adjoining room was a beautiful young woman of twenty-two, whom I had curetted for an extremely severe form of catarrhal inflammation. She had for years been in the habit of having a five- or six-weeks interval between her menstruations, and it so happened that her menstruation was due at the time that I did this hysterectomy. Until her period appeared, which was some ten days late, the complaints of the two women were identical, but their condi-

tions totally different—one with the whole of her internal organs of generation gone and absolutely nothing with which to let off the menstrual wave, the other with all her internal organs in place, the only difference being that the flow was delayed. Instances of this sort I could multiply from my hospital records by the hundreds; and all that we need is to have our attention called to it to recall scores of cases of the same thing. I think, therefore, that I may lay it down as a rule that if a woman's menstruation is for any reason, except pregnancy, delayed, she is very apt to have symptoms closely approximating those of the change of life. This leads me to believe that the internal secretion of the ovary is a myth. It is the last stand of those who have believed that the ovary dominates everything, and they have taken refuge in the recent experiments showing the immense necessity for glands that we know do have an internal secretion.

Some German professor, who heard his confrère in the chair of practice talking about the wonderful results from thyroid extract, was not going to be outdone in his scientific knowledge, and so assumed that the ovary also had an internal secretion, and immediately began giving ovarian extract to his hysterical patients. He, of course, obtained wonderful results. Some will ask, "How is one going to explain away these results?" We all know perfectly well that if we are positive enough with these hysterical women we can get results with anything. I have frequently succeeded with a combination of salt and soda. This was a suggestion of some of my level-headed nurses, who, after having become worn out with the complaints of some of these people years ago, found that the more horrible the taste of the stuff they gave them the more profound the result would be. Some will ask, "How about the results from transplantation of the ovary?" My answer is that they are so few and far between and altogether unsatisfactory that they probably belong to the same class. Those few who have been benefited have gotten it not from the ovary but from the disturbance of the menstrual nervous mechanism produced by the secondary operation. This has brought on menstruation which, as is well known, is the one great eliminator.

Twice in my life I have brought on a menstruation by removing the appendix. In neither case was the appendix in the pelvis, but lying tightly tied down to the psoas muscle, where the ligatures necessary to control the vessels of its mesentery had to go so deep that the nerve-trunks coming up from the pelvis were involved. The operations were done half-way between the menstruations, and at no other time had the menstruations returned in two weeks, but in both cases they followed in forty-eight hours after the operation; so with this experience I believe that if the menstrual centers in the cord have not degenerated, a disturbance of the menstrual nerves by any kind of an operation is liable to bring on an artificial menstruation, similar to one that follows the ordinary removal of the ovaries. This is reinforced by several other cases that I have seen, in which, without operation, appendicitis itself has brought on menstruation at times when it was not due.

Nature has its great cycles of rest and work. The alternation of the seasons is the one great object lesson which we constantly have about us. The rest of a plant during the winter corresponds to the condition of the woman in the intermenstrual period. The shedding of the leaves of the evergreen, the manufacture of its young leaves and buds, as we now see it around us, corresponds to the menstrual week. The shedding of the horns and hair of the deer is another analogy of the same sort. The molt in birds is another illustration of the same thing, for, as is known, the old feathers have to be dropped and new ones manufactured at a rapid rate. Those who have ever watched a pet canary will be struck with the similarity between its condition during the molt and that of our patients during the few days antecedent to the menstrual flow. The molt is always considered a critical time for birds. They all stop singing, breathe more rapidly, the exposed parts of their skin become more congested, and everything goes to show that an increased oxidation is going on throughout their entire body. The reason for this is shown in the rapid growth of the cores of the young feathers, which have to make immense masses of protoplasm in a short time. An analysis of their excretions shows that oxidation is going on much more rapidly than in the ordinary state.

Just so it is with the woman. When the time arrives for the menstrual pressure to begin, associated with the congestion of the pelvis is an increased oxidation of the whole body, and, as I have maintained so often, and which has been so thoroughly proven by Jacobi, Stephenson and other workers, the result of this oxidation is an increased amount of excretion of every description. The majority of women stand this beautifully. The reason for it is this, if I may be permitted the illustration of a furnace. The draft is what it should be, the grate-bars are properly placed and the fuel burns up completely and passes off through the chimney, the ashes fall out into the ash-pit leaving no clinkers, coke or cinders behind. But, unfortunately, the furnaces of many people are defective in construction. The flue does not draw as it should, the grate-bars do not let in the required air, and the consequences are that the chimney gets choked with soot, and the fire-box retains cinders, clinkers and fuel in different degrees of consumption. For the lack of a better term these people have been classed as the "gouty," and they are the very people who give us the greatest trouble at the menopause. I have often said that if I know the family history of a patient, I can tell positively whether she is going to have trouble in getting through with the change of life. As we all know, here in America, we do not have gout

to any great extent in its explosive forms, but in our dry climate these poisons exert their action on the nervous system, so that our patients with sick headaches, migraines and general nervous conditions are the lineal descendants of European families who were loaded with gout. Haig is undoubtedly on the right track. I do not claim that uric acid is the poison which causes all this trouble, but I do know that the uric-acid group has a great deal to do with it. My friend, Dr. Rachford of Cincinnati, has done a great deal of original work in this particular line, and I am indebted to him for most of the suggestions that have guided me in the handling of these troublesome cases. He has proven beyond a doubt that in addition to uric acid there are many poisons that belong to the nitrogenous group.

We know that urea is the complete oxidation of a nitrogenous compound; that uric acid is the same material, but not completely oxidized; that the various xanthin bodies are the same substance, but still less oxidized, with paraxanthin at the foot of the group in the shape of a nitrogenous body that is only very slightly oxidized.

To take the illustration of the furnace again, urea corresponds to the ashes at the bottom of the pit; uric acid to the coke still left lying on the grate-bars; the various forms of xanthin to coal less and less burned, until we come to the paraxanthin, which is the coal little more than charred.

Dr. Rachford's work has turned on the poisonous properties of these various nitrogenous bodies. He has proven that paraxanthin is the most poisonous of all; also that where we have large quantities of uric acid in the urine some of these xanthin bodies are apt to be found. Several cases of hystero-epilepsy in my practice have been proven to be directly due to the presence of xanthin bodies and the epileptic convulsions were nothing but the characteristic symptoms of its toxic effect. By increasing the oxidations of these patients he has gotten rid of the paraxanthin, and although some of the cases were four or five years old they now remain perfectly well.

It would consume entirely too much time to go deeply into this subject, but those who are interested in it will find it in the Transactions of the Association of American Practitioners, where a great deal of notice has been taken of it. It is true that Dr. Pfaff has found that the presence of ammonia in Dr. Rachford's final fluids has intensified the effect of the poisons, but as we all know that ammonia in itself is not specially poisonous and that without the paraxanthin it will not produce any such symptoms unless it be given in large doses, it only proves that the ammonia compounds of the xanthin bodies are more readily diffusible and more violent in their effects than the substance in its pure and simple state. This is a condition, however, of many drugs—the salt has a more violent effect than the pure article.

Many menstrual headaches are undoubtedly due to something of the same cause. The increased oxidation of menstruation in a gouty subject will increase the number of poisons toward which the patient has a tendency; for this increased oxidation in a menstruating, gouty woman acts like the throwing of more fuel on an already smoking fire.

Assuming that this is the cause of not only menstrual but menopause difficulties, I have for years treated all my cases of either sort by increased elimination, and I am happy to say with uniformly good results. I have had but two cases which gave me trouble in getting them through with the artificial menopause, and both of them were in markedly gouty females. One of them had an uncle, a practising physician, who brought the patient to me after a violent attack of peritonitis that necessitated the removal of the appendages. She made a prompt recovery from the operation, but in the years that followed it was interesting to note how her symptoms corresponded with those of her uncle. It was nothing more than hereditary gout accentuated by the attempts at increased oxidation every twenty-eight days.

The other case was similar in every respect. A markedly gouty history, with a chronic peritonitis that demanded a life-saving operation, although she gave me a great deal of trouble for the first year; finally Dr. Rachford succeeded in making her very comfortable.

Dr. Rachford's work is not yet complete on these bodies and it would be unjust to him to anticipate, but I can say that, thus far, his results have been extremely satisfactory as applied to my work, that in addition to the xanthin bodies we will ultimately find a great many other poisons which are the results of faulty oxidation and its resultant elimination.

So, then, I repeat, there is not an iota of proof, either from analogy or experience, that the ovary has any kind of an internal secretion, but that the troubles which accompany the menopause, both natural and artificial, are due to a faulty oxidation and excretion.

One other cause of this condition is due to the intestinal infection that goes with nearly all these cases, and this allows the colon bacillus and its associates to contaminate the nitrogenous bodies with their ptomains before they are absorbed into the blood. Faulty excretion allows the liver to become "stagnant," as the old practitioners used to say, thus interfering with the circulation of the portal vein. This allows the germs of the intestine to lodge in its epithelial lining. This subject has been discussed frequently, especially in that memorable paper of my old teacher, Dr. Goodell, on the hysterical rectum. Each effort at an increased oxidation only adds to the trouble of a sluggish portal circulation, and thus invites the very condition I have described. This gives one more proof of the necessity for a careful study of the menstrual wave in all its bearings. Until we get rid of the old superstition of "ovarian influence" and similar terms which we have

heard for so many centuries, the reproductive functions will never be thoroughly understood. The last few years' experience has taught me to believe firmly that the ovary, in itself, has little or no influence even on the development of a woman and much less on her well-being after menstruation begins.

Some eight years ago I removed both ovaries from a little girl of eleven who had never menstruated, for double ovarian tumor. She was in every sense a child, and I thought there would be one case of a true female eunuch. What was my surprise a year or so ago to have one of the most beautiful women I ever saw walk into my office. It was this same child come back to show herself. I examined her carefully. Her figure had rounded out to perfection, her breasts were very large and perfectly developed; all the external organs of generation and the vagina were perfect, and the hair on the mons thick and fully grown. In every sense she was as perfect a woman as I ever saw, except that she never menstruated. More than this, she has a beautiful voice.

You will ask how this happened. My belief is that the sexual centers had already begun to develop before the ovaries were removed, and that was all that was necessary to produce every sign of puberty except menstruation. I would wish that others would look up these cases, because I know that many practitioners have had more of them than I have, and I would like to know whether these girls who are operated on before menstruation begins usually develop into full womanhood. If this is the case, the ovary will have to be relegated to the function of producing eggs alone. When we see every other organ in the body controlled by the central nervous system, why is it that we will persist in saying that this one little epithelial body contains all the functions known to womanhood? The only reason that I can see for it is that it originated in an old superstition, and, like every other superstition, will last as long as men will consult the moon before planting their potatoes.

Some will ask, What, then, are my beliefs as to the limits of conservative surgery? My answer is, Where an ovary and its accompanying tube can be left in a healthy condition so that their functions can be easily and safely carried out they should be preserved, but I have nothing but condemnation for those dangerous experiments which result in the leaving of a scrap of one ovary in one part of the abdomen and a piece of a tube in another, or the transplantation of an ovary from one patient to another. Suppose that we could accomplish what we desire—the preservation of menstrual life—what good would it do? It is only postponing the menopause; and the troubles that a woman has at the menopause are hereditary, and what difference does it make whether she goes through them early or late? All of this talk about the shrinkage and atrophy of the external generative organs at the artificial menopause has not held good in my experience, except where I have been careless enough to overlook a metritis or vaginitis. In a few cases of this kind, in my early practice, I did have a form of cirrhosis of the vagina set in, but after I found that that was the cause of the trouble and proceeded to cure it with yellow oxide of mercury, I have had no more trouble of this kind.

In conclusion, I would say that all of this furor about the internal secretion of the ovary only results in bad work, as it gives a cloak for leaving patients in dangerous conditions, and an excuse for not doing the tedious part of our clinical work.

INTERNAL ANTISEPSIS.[1]

By REYNOLD WEBB WILCOX, M.D., LL.D.,
OF NEW YORK;
PROFESSOR OF MEDICINE AND THERAPEUTICS IN THE NEW YORK POST GRADUATE MEDICAL SCHOOL AND PHYSICIAN TO THE HOSPITAL; PHYSICIAN TO ST. MARK'S HOSPITAL.

I AM fully aware that in presenting this subject I am giving opportunity for the expression of widely divergent opinions and that I am entering upon a territory which has been the field of fierce combat. But when this discussion shall have been finished I am sure that, if the distinguished gentlemen who have taken part are not entirely in accord as to its possibility or the means of accomplishing it, they certainly will agree that some method of attaining internal antisepsis is desirable and that, at least, some progress has been made toward it.

It goes without saying that in the treatment of infectious diseases lies the field of internal antisepsis. Strictly speaking, then, in septicemia, this should be useful and possibly in some pyemias the pus foci of which are not accessible to the surgeon. In presenting this subject surgical methods are not decried, but, on the contrary, as prevention is of far greater importance than cure, any infection-focus capable of being treated surgically should receive that kind of attention. This paper is not a plea for the substitution of medicine for surgery, but for a method of combating infection when surgery fails.

1. Is internal antisepsis possible? If we assume that the picture usually presented by septicemic patients denotes general infection, and that these symptoms—chills, malaise, headache, fever with remissions, restlessness, marked prostration, sweating, muttering delirium—and these signs—red and glazed, later leathery tongue, a full and bounding pulse which later becomes compressible, enlargement of the spleen and hypostatic congestion of the lungs—indicate septicemia and establish the diagnosis, that under the administration of remedies which are taken into the circulation these symptoms and signs are relieved and become less evident and finally recovery ensues, the suspicion may be entertained

[1] Read before the Medical Association of the Greater City of New York, May 14, 1900.

that the remedy may have been the cause of the recovery. If this association of remedy and relief becomes absolutely constant, or fairly constant with explainable failures, the suspicion may become well established opinion. To be an antiseptic, a remedy must either prevent the growth of, or completely destroy, the micro-organisms. To be efficient the substance must come in contact with micro-organisms wherever found. That micro-organisms have as wide an area of distribution as the blood is well known. If an internal antiseptic is efficient not only must the symptoms referable to bacterial activity be diminished or abolished, but evidences of their presence must be wanting in the excreta, sputum, feces, and urine. Let us see how far each method of demonstration may be applied.

Enteric fever is beyond question an infectious disease. The later stages, at least, are the full development of septicemia. Chlorine, as I pointed out in my Albany paper in 1895, cleans the tongue, improves appetite and digestion, lessens the fever, and frees the stools from odor save that of the drug used. The general strength, intellectual processes and nervous conditions improve. The disease is shortened in duration and usually proceeds to a rapid and complete recovery. The histories embodied in my first report were those of long-continued enteric fever, observed at Bellevue Hospital, and usually promising but little hope of successful treatment. My second report in 1899 was based on quite as difficult subjects—returned soldiers from the Spanish war—and was equally emphatic. The observations merely confirm the experience of East Indian physicians who have employed chlorine for many years. More widely known are the papers of Yeo on this subject.

The second method of obtaining confirmatory evidence, by examination of the sputum, has been practised with considerable success. The administration of creosote, especially the carbonate, when prolonged is followed by a diminution of the number of the bacilli of Koch found in the expectoration, as has been shown by Holscher and others. Certain volatile substances which are excreted by the respiratory surface are efficient, particularly the terebene obtained from the *melaleuca*, as has been demonstrated by Forne.

The third method of proof is illustrated by the observations of Bouchard upon the results of the administration of naphtol for various conditions found in the alimentary canal when the number of pathogenic bacteria found in the feces was very markedly diminished. Quite in harmony with these observations were those of Hueppe, who found that no cultures could be made from the intestinal contents of a patient who had died from apoplexy supervening during Asiatic cholera and who had been treated by bismuth tribromophenolate exclusively. In other and exactly similar instances, when tannic acid injections had been used, cultures were made without difficulty.

There is a necessity for important work in examination of the feces to note the results of the administration by the mouth of various antiseptic and germicidal substances, which I trust may be recognized at no far distant time.

By the fourth method of proof, examination of the urine, we may establish certain facts. It has been known for some years that the large majority of patients suffering from enteric fever discharge large numbers of the bacilli of Eberth in their urine. Quite recently Richardson, Horton-Smith, Gee and Andrews have demonstrated that hexamethylen-tetramine will cause an entire disappearance of these bacilli when it is administered by the mouth. A method which has been employed for determining the value of certain plans of treatment calls for a word in passing. I refer to the urinary toxicity and its observed variations. While changes in the urotoxic coefficient might be assumed to indicate variations in the elimination of toxins by the kidneys, this method of research was sufficiently seductive to have led several observers to place faith in it as an accurate method. Since, however, it has been shown that even urine from presumably healthy individuals when injected into animals produces varying results, according to the species to which the animal belongs, and further inconstant results even in animals of the same species, the findings from injections of urine from infected subjects are still more unreliable. Until we have a method of obtaining the amount of toxins excreted by physical or chemical methods this plan should be abandoned, as giving rise to misleading results.

2. Can it be detrimental? To this question must be given a decided affirmative answer. The fact is well known that certain substances which *in vitrô* are most trustworthy antiseptics are poisonous in the body. Instances of fatal poisoning by phenol, iodoform, corrosive sublimate and others, are too frequent to be ignored, and these must be eliminated from the list of remedies which we may employ for the purposes discussed in this paper. Those substances which are locally irritant act unfavorably upon tissues or destroy blood corpuscles must be barred. One question is frequently raised—and particularly with reference to intestinal antiseptics—are not bacteria essential to digestion and absorption? In rendering the alimentary canal free from pathogenic bacteria, are we not interfering with the nutrition of the patient? While it is true that certain loosely-held chemical compounds, as salol, bismuth salicylate and others, are broken up by bacterial activity, the preponderance of evidence is largely against bacteria of whatever kind being necessary. Confirmation of this opinion which is held by Nencki, Nuttall and Thierfelder is furnished by Levin from his observations in the Arctic region. While there he found that the intestinal contents of polar bears, seals, eider ducks, and other birds, sharks, sea-urchins, anemones and crabs, were nearly always sterile. Neither could cultures be made nor bacteria be found.

3. Under what conditions may it be employed? In the first place, any focus of infection which is amenable should be treated by surgical intervention. Further, infections resulting in septicemia in which the toxins are most potent in causing danger should be neutralized by antitoxins. I refer especially to diphtheria, in which the toxin elaborated by the Klebs-Löffler bacillus is presumably more important than the bacillus itself. On the contrary, in those cases where streptococcic infection is of most importance, either as primary or secondary, and where the serum treatment is at best not thoroughly established internal antisepsis must be carried out. As for the condition of the patient, great care must be exercised in administering remedies which may act unfavorably on the heart or kidneys. For instance, in acute polyarticular arthritis, which is nowadays generally admitted to be an infectious disease, salicylic acid must be given with caution if the kidneys are not sound. Also, in chronic dysenteries naphtalin will produce violent cystitis if any irritation of the bladder be present. Almost all of the phenol series are marked heart-depressants and should be administered with care to those whose hearts are incompetent. Naphtol and some of its derivations produce acute indigestion; this list might be further extended. To sum the matter up in a few words, kind Providence is just as watchful over the pathogenic bacteria as over their unwilling host and care must be exercised that in destroying the enemy the patient does not suffer. Obviously, when structural degenerations have become established, this, in company with all other forms of treatment, fails. Lastly, a recent writer may be quoted with profit, as follows: "Bacteriologists often make the mistake of denying the efficiency of minimum doses of so-called intestinal antiseptics, simply because the bacteria were not killed by their agents; they forget that exceedingly small quantities of these substances might paralyze the bacteria and prevent them from forming toxins, even though powerless to kill these organisms."

4. How is it best obtained? This may be best considered by dividing our agents into groups.

(*a*) The general internal antiseptics, such as chlorine, silver, the salicylates and quinine. Chlorine has been known as a disinfectant from the time of Halle (1785). When administered by the mouth it is in part changed into chlorides by combination with alkaline bases in the stomach or blood and in this form is excreted by the kidneys. Edwards, however, showed that all is not so combined, for in a fatal instance of enteric fever the necropsy showed enormous ulcerations in the intestines which were dyed a greenish-brown color. If inhaled it permeates all organs and tissues and even penetrates to the brain. Cameron reported that in a fatal instance of chlorine-poisoning, the distinct odor of chlorine was perceived in the brain. Further evidence is to be found in the fact that when administered by the stomach, the nose being held, the odor of chlorine is noticed in the breath within a few minutes. Locally, chlorine is irritating, quite so to the respiratory and but slightly to the alimentary mucous membrane. If given internally in moderate doses it quickens respiration, increases the force and frequency of the pulse and excites the functions of the organs of secretion, notably increasing the flow of saliva and of bile, the latter an antiseptic of no mean value. Because of its action on the kidney it is presumed that the toxins already formed are more rapidly eliminated. As factors of less importance are its stimulating effect upon the heart and increased digestive power. In the treatment of enteric fever the results already noted are quite constantly obtained. The class of cases for which I have reserved the use of chlorine are those which have come under my observation late in the course of the disease. They have frequently run the gamut of the so-called Brand treatment, either mitigated or unmitigated, expectant or hopeless methods or even of intelligent let-alone management. The chlorine water of the Pharmacopœia, freshly made, in doses of from one to four fluidrams every two to four hours, well diluted, has been amply sufficient. After reading Sanulli's argument a few years ago that in this disease the intestinal lesions are the result of the toxins circulating in the organism infected by the germ of Eberth, and that this is the principal cause of the material manifestations and morbid phenomena which go to make up the clinical picture of enteric fever, I was tempted to commence the treatment in its early stages with chlorine. Formerly, I had employed such insoluble antiseptics as bismuth naphtalate, various preparations of salicylic acid and naphtalin. In a few instances the results were not satisfactory from a clinical standpoint, so that I was forced to believe that Sanulli was wrong in his conclusions. How far chlorine may be of use in other infectious diseases I am not at present prepared to state. In a recent instance of septicemia, resulting from a pulmonary abscess consecutive to a septic pneumonia, although the interval between the extreme oscillations of temperature were appreciably lengthened and the fetor of the breath lessened, the amplitude of temperature excursion was not diminished.

Silver has been recently suggested for use as an internal antiseptic. It was about 1890, I think, that Carey Lea showed that silver existed in allotropic form. Seven years later Credé made use of colloidal silver, so-called, in medicine. This is almost entirely soluble in water and albuminous fluids and seems to inhibit the action of staphylococci and streptococci or destroy them altogether. For internal use, to prevent its conversion into a chloride in the stomach, it is first dissolved in equal parts of albumin and glycerin. Since it is unirritating, it may be administered hypodermatically in aqueous solution. In the early days of its employment it was rubbed in a fifteen-per-cent. ointment. Resort has been had to rectal and intravenous injections.

The dose is about one-sixth of a grain, two or three times daily. Credé claimed that it had a very beneficial influence and often affords a rapid cure in recent and also in chronic sepsis and furunculosis, when secondary changes in vital organs have not occurred. Various conditions have been treated; osteomyelitis, phlegmonous angina, furunculosis, erysipelas, so-called gonorrheal and articular rheumatism. Various reports, some very enthusiastic, have been presented; on puerperal fever (Peters, Jones, Voorhees), cerebrospinal meningitis (Schirmer), acute mastitis (Cumston), malignant scarlet fever (Credé), diverse septic processes (Werler), furunculosis (Wolfram) and, finally, purpura in the horse (Dieckerhoff), which according to this author is due to the introduction of a special virus into the blood of the animal. Schlossmann has shown that this substance is non-toxic and unirritating to mucous membranes. Thus far no instance of argyria has been reported. My own experience with septic phlebitis in which an unusually large percentage has occurred in patients suffering from enteric fever has been more satisfactory. Here it has been employed by inunction for thirty minutes. In one instance of septic phlebitis following amebic dysentery the results were almost marvelous.

The use of the salicylates in acute polyarticular rheumatism is too well known to require more than passing mention. The only point of importance, not generally considered, is that while salicylic acid is antiseptic the salicylates are not; the question is, therefore, to choose substances which yield salicylic acid within the organism. Malarial fever is a disease resulting from an infection if the investigations of Ross, Manson and Bignami are accepted. Quinine, then, preferably as a carbamide, given hypodermatically, is a method of internal antisepsis applied to combat an especial infection.

(*b*) To combat infectious processes having their most active manifestations in the alimentary canal is no new problem. Many methods of treatment depending more or less upon internal antisepsis, sometimes without credit to the method, have been advanced. Naturally, a clearing out of the intestines is of the same order of procedure as the evacuation of an abscess. Bile is claimed, certainly with some reason, as an intestinal antiseptic. Others, regarding the alimentary canal as a sewer, abandon all hopes of even measurably freeing it from bacteria. Still others unknowingly testify to the value of intestinal antisepsis by giving hydrochloric acid or small doses of calomel in enteric fever.

Among remedies most useful for intestinal antisepsis may be reckoned various insoluble substances: Naphtalin, betanaphtol, and various bismuth compounds. As long ago as 1887 I reported my observations with naphtalin in the treatment of some old army dysenteries. This, however, sometimes produced vesical irritation and other untoward symptoms. Betanaphtol was found to be too irritating to the stomach, so that although the reports of Bouchard were positive as to its antiseptic action its use was abandoned. Salol was effective in many instances, but its use presupposed sound kidneys, and in the presence of fever or too acid contents of the duodenum it was not decomposed into its constituents. The bismuth compounds were not irritant and their use has been crowned with success. Two have been especially studied, the naphtolate and tribromo-phenolate. In his experiments with the former Jasenski found that while the bismuth was almost completely excreted by the bowels, some of the naphtol was eliminated by the kidneys. In daily dosage of seventy-five to one hundred and twenty grains for an adult it is certainly not poisonous, and the quantity is quite sufficient to inhibit bacterial activity. The literature has been extensive and, in general, confirms my personal observations. As for the tribromo-phenolate the observations of Fasano are quite conclusive. After the administration of this remedy the amount of indican in the urine was markedly diminished, as was also the amount of putrefactive action in the intestines. After five days the feces of patients suffering from enteric fever gave no cultures of the bacilli of typhoid fever and bacterium coli. Intestinal tuberculosis, in some instances yielded to emulsions administered either by the mouth or rectum. Apparently in this substance, the tribromo-phenol is slowly liberated so that no poisonous symptoms are produced, although the daily amount may reach over one hundred grains. Some of it, at least, passes out through the urine, for Reynders has been able to detect tribromophenol twenty-four hours after the absorption of the drug.

During the past three years another bismuth preparation has attracted considerable attention. I refer to the tetraiodophenol phtalinate. The laboratory studies of Klebs, Kruse and Lieven made with the sodium salt furnish evidence of its antiseptic action. The consensus of opinion seems to be that it is harmless and yet efficient. The only untoward effect which has been observed was an iodine acne which promptly disappeared. Bacteriological experiments made with the sodium salt indicate that it is effective against various pathogenic bacteria, notably staphylococci, streptococci and the bacilli of enteric fever (streak cultures on agar Petri plates). This differs from the other bismuth compounds in that it is, according to Loeb, at once split up by the gastric juice into bismuth oxychloride and tetraiodophenolphtalinate in which the iodine is certainly important. The necessary dose is somewhat smaller, five grains, thrice daily, being sufficient.

(*c*) Remedies for internal administration which have been designed to act upon the bacilli of tuberculosis are too numerous to be mentioned. Creosote has generally been conceded to be useful in the treatment of pulmonary tuberculosis since 1833, when it was employed by Reichenbach, to the present time. The disadvan-

tages of even beechwood creosote are well known. The non-toxic and unirritating carbonate and perhaps other derivatives and guaiacol carbonate have thoroughly supplanted it. While I am sure that no one can claim that creosote is germicidal, as regards the bacilli of Koch, we are sure that it renders the soil upon which these flourish unsuitable for their growth; in other words, it inhibits their development. Twenty to sixty drops thrice daily in sherry or port seems to be efficient. As to its value in pneumonia we have the testimony of Thomson, Smith, Cassonte and Corgier. Guaiacol carbonate is certainly harmless if we place credence upon the laboratory study of Eschle. Of this four to seven grains four times daily are sufficient to yield good results. Quite recently a glycerol ether has been lauded by Butler, but of this I cannot speak from personal experience.

Quite lately I have undertaken the investigation of a terebene derived from the *Melaleuca*, which is probably a mixture of three products, eucalyptol, terpineol and possibly citrene. This is excreted by the lungs and since it is unirritating can be administered hypodermatically. It is quite too early to report results.

(*d*) Of all the remedies which are classed as urinary antiseptics, hexamethylen tetramine probably stands at the head. This substance, a condensation product of formaldehyde and ammonia, dates back to 1860 when it was made by Von Butlerow. Its use is to sterilize the urine by destroying micro-organisms which it does effectually and finds ample field for its employment in pyelitis, pyelo-nephritis and cystitis. Even large daily doses, to one hundred and fifty grains, are well borne, although these are entirely unnecessary. Nicolaier employs about eight grains, thrice daily. Formaldehyde is liberated in the urine and this, even in the smallest quantity, prevents the development of micro-organisms. Richardson finds that a constant result of its administration to patients suffering from enteric fever is the freeing of the urine of the bacilli of Eberth. A personal observation in regard to the bacillus of Koch is that the urine of a patient afflicted with tuberculous cystitis shows a much smaller number of bacilli during its administration, but a continuance of the medication is necessary.

I am aware that this subject has been presented in a fragmentary and incomplete manner. My purpose has been to point out what has been accomplished by many observers, and how far the answers to the questions propounded in this paper may be justified by the facts at our disposal.

Thirty years ago the foundations of surgical antisepsis were laid and the development upon these foundations brought about by Lister and countless followers has resulted in the ideal having been nearly attained. To-day one may consider that internal antisepsis rests on quite a secure a basis as did the surgical when the pioneers began their work, and the ensuing three decades will doubtless bring to fruition our most daring hopes. As the surgeon gives credit to Lister, so must we acknowledge our indebtedness to Bouchard for many of our facts, trusting that others will continue the work which he so painstakingly has begun. At this time, we can safely say that internal antisepsis is more than the dream of the theorist.

Internal antisepsis is possible, may be useless or detrimental under certain conditions, or may be absolutely contraindicated, because of the patient. How best to attain internal antisepsis is a question to which the answer will vary with each succeeding year as our knowledge of infectious diseases and the best means of combating them rest upon a broader and more secure foundation.

THE TREATMENT OF CONSUMPTION AT HOME.[1]

By JOSEPH EICHBERG M.D.,
of Cincinnati, Ohio.

No single subject of general interest to the practitioner has been attracting so much attention recently as the topic chosen for the subject of this paper. The fact requires no explanation. The widespread prevalence and high mortality of pulmonary tuberculosis are so well known that statistical data of every kind would be superfluous. The ceaseless interest that has attached to the study of all questions connected with consumption, so-called, is evidence of the importance of the study to the physician and to the community. The enthusiast may devote his life to the elucidation of an idea or of a speculative problem. It is the practical question which enlists the patient, persevering effort of many workers.

It cannot be said that the treatment of consumption may be ranged in the category of questions that have nearly found solution. No one would think of classing it in this respect with diphtheria or malaria or syphilis, or even with diseases not yet amenable to treatment by specifics, such as rheumatism, pneumonia and typhoid. But the problem may be considered as approaching solution.

The promise thus held out to the consumptive and to his family does not come to them with the glamour of specific and prompt effects to be obtained from the use of secret nostrums or of semi-quack remedies. There is to be no wonderful change wrought after the fashion of the Arabian Nights' performances, where the good genius anoints the patient or injects him with his little syringe, and the unhappy sufferer emerges radiant in his new equipment of health. No "open sesame" shall instantly remove the bars of the sick-room; but honest, patient, intelligent endeavor shall aid the patient in his

[1] Read before the Ohio State Medical Society, Columbus, May 10, 1900.

battle against the malady that oppresses him and, in many instances, turn the scale in his favor.

It would almost seem that in this one feature —the treatment of pulmonary tuberculosis—the researches of science had not been an unmixed blessing; or, rather, that the light shed upon the subject of causation, preeminently by Cohnheim, Villemin and Koch, had served rather as a will-o'-the-wisp than a true beacon. Given a specific germ or bacillus as the cause of the disease, what more natural than that the next aim of all research should be a specific remedy, a parasiticide? The more recent advances in our knowledge of immunity, the discovery of the antitoxins of diphtheria, tetanus and of the bubonic plague, all tended but to stimulate the search for a similar remedy for the relief of a disease, whose annual mortality exceeds that of the most virulent and destructive of all epidemics.

Thus, it has come about that we have wandered afar from what seems to be, if not the true, at least the safest path; and now that we have followed the different marsh-lights, our feet return to the old road; we are somewhat wiser for our various errors, with some illusions gone, with our experience as a safeguard against too eager pursuit of every chance, but with courage undaunted by past failure and with earnest undiminished hope for further success.

It is not difficult to see why we have strayed. All therapeutists, in the pursuit of the *specific* idea, seem to have lost sight of the fact that pulmonary tuberculosis in the only forms which are amenable to treatment, that is to say, in its chronic forms, is always either a mixed infection or a process so limited in its distribution that natural safeguards will surround the tuberculous area with an investing capsule and thus make it harmless.

The term consumption is wonderfully well chosen. It characterizes, as perhaps no other single word could, the dread course of the malady and furnishes the reason for its fatal ending. It is the consumption of tissue, of strength and of resisting power, so far in excess of the power of repair, that leads to the "decline," another polite term for the same process. The suggestion comes almost spontaneously that a cure is only to be sought either by arresting the waste, or by so increasing the assimilation that the balance will remain on the credit side of the patient's ledger. It would appear that whatever agencies can increase the assimilation of nutritive material not only furnish substance to replace that which is lost, but that this very increase of constructive metamorphosis promotes directly that increase of resistance which stays the destructive agency. We not only get an amount of good money equal to the bad, but we prevent the bad money from being put into circulation; we not only put on a pound for the one that has been taken away, but the new pound thus formed causes the slower removal of the next pound; the patient thus being steadily strengthened for his battle.

The treatment of consumption may be properly classified as the specific, the climatic, and the dietetic and the hygienic. Some allusion has already been made to the specific treatment. The search for such has flooded medical literature at different times with the most curious suggestions. The remedies most prominently mentioned in recent years have been the various derivatives of the tubercle bacillus; the original tuberculin of Koch, his later tuberculin R.; the tuberculocidin of Klebs; the special forms of culture products the secret of which remains with their discoverers—and advertisers; the phosphorus combinations, under the supposition that the causal element was a deficiency of phosphorus; the hot-air inhalation treatment, the injection of cinnamic acid and the absurd treatment of Bergeron of inflating the bowel with sulphuretted hydrogen, were all dominated by the one idea of curing the disease by killing the poison that was its cause. The futility of such efforts, easily understood when the pathological substratum is taken into account, is now generally conceded by the majority of the profession. With regard to tuberculin, the acts are not yet closed, in spite of the clear unchallenged demonstration by Virchow that the introduction of this product into the circulation often occasioned a general dissemination of a previously localized process; and thus furnished the means of undoing what natural efforts, unaided, had accomplished for the arrest of the disease.

Creosote was also introduced, originally for its specific action. The idea that it possesses such power is no longer current—the tubercle bacillus is not likely to be reached by the remedy in any such concentration as could impair its vitality or retard its growth—yet creosote continues rightfully to hold an important place in the treatment, because in small doses it seems to promote digestion, to increase appetite and thus to favor those natural forces through which the return to health is made possible.

It is fair to presume that the search for specifics is not yet done nor likely to be given up. The prize is too great, the reward too tempting, whether considered from the broad side of humanity, or from that of material gain, but the philosophy of past experience would seem to show that the patient's safety does not lie in that direction.

The climatic treatment deserves more than a passing mention. It has proved its title by many victories; it has withstood the reproach of many failures. Without reference to the advantages or the disadvantages of any geographical zone or altitude, the great difficulty in its application is the limited number of patients, whose pecuniary circumstances will permit them to take advantage of it. With the wide prevalence of consumption, the great fraction of its victims must always come from the working classes whom removal from home and a life of contin-

ued idleness are alike impossible. Even where pecuniary considerations do not enter into the question the victim will often prefer the certainty of speedy death to the possibility of recovery in exile, removed from home and kindred. The patient sent away for his health, with the necessity for completely severing all business and social ties, finds himself among strangers without any anchor. His heart, too, like that of Goldsmith's Traveler, "drags at each remove a length'ning chain." The very fact of his want of occupation makes him an easy prey for nostalgia, so intense that it may prove almost fatal. There can be no greater suffering, even in physical pain, than that occasioned by such attacks of homesickness. It is because their life's work may be resumed even in new abodes that physicians, who are forced to try a change of climate because of pulmonary disease, show more rapid and permanent improvement than patients from other callings. When the patient is fairly settled in his new quarters he whiles away his hours with others, who, like himself, have sought "some air, some weather, and some earth." He fortifies himself, in the language of Robert Louis Stevenson, with "tonic, bitter wine and perpetual beef tea" or "sooks awa' at codliver ile till it's a fair disgrace."

Let me not be misunderstood. I would not underestimate or speak lightly of the benefits of climatic treatment in this disease. Indeed, there are many cases in which it would be gladly undertaken, if patients could have anything like a fair assurance that the banishment would not be permanent; that, after a stay of a few months in the selected spot, they might return with a reasonable hope of a comfortable existence. I believe that it is the combination of climatic treatment with the succeeding home treatment that will often yield the best results. Many a patient will bring the sacrifice, of money and of sentiment, exacted by a removal from home and the cessation of business activity, if there is a fair promise that the benefits accruing will not be more than neutralized by his resumption of a life at home.

The great majority of our consumptives must remain where circumstances have placed them. For them, for the suffering poor, the third plan of treatment, the dietetic and hygienic treatment, holds out a ray of hope so promising that it requires only determined effort on the part of the profession to rob the dread disease of many of its terrors. The dietetic and hygienic treatment may be summed up as consisting of good air, good food, good rest and good cheer, and there should be an abundance of each.

Our opinions of the value of "good air" in the treatment of pulmonary consumption have undergone no change; it is merely a question as to what constitutes good air, and how it should be administered. The impression has been general that rarefaction was an essential feature of good air, and for some time it was held that an altitude of 6000 feet, or thereabouts, was indispensable. While not denying to the atmosphere at this altitude the advantage of purity sufficient to make it of special therapeutic virtue, it has been shown that much lower altitudes will answer quite well for consumptive patients. Thus, the famous sanatorium at Nordrach in the Black Forest is 1400 feet above the sea level, Ventnor on the Isle of Wight, and Bournemouth on the southern English coast are practically at the level of the sea. The results obtained by Detweiler at the Sanatorium of Falkenstein in the Taunus range are familiar to all. But the rapidly accumulating experience of the past few years, gained largely at the various sanatoria, has already established the fact that no air, even when seemingly most unfit, such as the atmosphere of the crowded city, is altogether objectionable, provided it be the air of outdoors. The warm, stuffy, oft-breathed and much contaminated air of the ordinary living-room, no matter how spacious the dimensions, is unfit for the tuberculous patient. It has just been said that some air is better than others; naturally the free, pure, quick-shifting air of the higher altitudes will fill the requirements better than the soot, dust and gas-laden atmosphere of the large city, yet the latter still contains all the ingredients sufficient for the patient, whose progress in this medium will be somewhat slower, but there will be progress.

It is particularly for the purpose of showing that this atmosphere forms a medium not wholly unfit for the lungs of the tuberculous patient that so much recent work in the direction of the home treatment for consumptives has been undertaken. The most noteworthy feature in the reports of recent studies is the uniformity of success under climatic conditions the most diverse. From large cities, such as Manchester, England, practically at the sea level, with considerable moisture, in inland and upland villages, in small sanatoria in England, Ireland, Scotland and Wales, in Germany and France, and in our own country, most encouraging accounts have been furnished. We may thus safely feel that we are not of necessity bound to any climate or altitude; we may take advantage of the more favorable conditions offered by these, when the circumstances of the patient, pecuniary and otherwise, permit; but we have no right to despair or give up the battle because the patient cannot be sent from home.

Granted that the patient shall receive the air fresh from outdoors, how much shall we give him? To begin with, about twenty-four hours worth every day. The patient must live out of doors. In winter he does this by being warmly muffled up in fur and blankets, with hands and feet well covered and sitting or lying in the open air in the sunshine if possible; protected from the wind, if need be, by a small canvas screen. If there is rain or snow, a glass-encased veranda will supply the place of the solarium of the sanatorium; or a canvas cover to the veranda, leaving an opening for free access of air, will an-

swer very well. The patient rests out-of-doors and must therefore be well covered with clothing and wraps. In summer the shady spots in the open will naturally be sought. At night the windows of the bedroom are kept wide open, winter and summer. The excessive cold of the winter night may be tempered by a grate fire in the open hearth, but fresh air must enter freely from without. Dr. Millett of Brockton, Mass., in a recent report to the *Maryland Medical Journal*, has shown the courage of his convictions by having five of his patients sleep out-of-doors during five or six months respectively, from June to November. A platform was built at the height of the second floor; on this the patient's bed was placed; and here, except on rainy or stormy nights, he slept soundly and comfortably; never being the worse for the dews or even for light drizzling rains.

Where the patient can be induced to do this, there would seem to be sound reason for preferring the canopy of heaven to the restricted space of the bedroom, however free its ventilation. With firm persuasion on the part of the physician the first objection to such a change in the patient's way of living can usually be overcome, although the rank heresy that night air is harmless, flying, as it does, in the face of all established tradition, always causes a prompt objection. Later the patient's own judgment can be left to deal with the problem. So marked is the improvement, so decided the change, that the consumptive will soon complain of the oppressiveness of the air in any room with closed windows. When not in the open air, it should be made a rule that the temperature of the living room during the day should not exceed 65° F., and for five or ten minutes of each hour the windows should be left open, even in the most severe cold. Along with other fallacies we have swept away the bugbear of taking cold when a breath of fresh air enters the living room of the consumptive patient. The impure, hot air weakens and enervates; the cold, fresh air revives and exhilarates the patient. Fresh air in abundance comes first in the treatment, because fresh air means better appetite and better sleep, better oxidation, better nutrition.

Next to good air we place good food. Of this, too, there must be an abundance. It will be the physician's duty to crowd the food as he has crowded the air; and it will require more tact and persuasion. There is at times an actual aversion to all food; at others, a strong repugnance to those simple nutritive aliments that come under the head of the easily digested varieties. Meats and fats are special objects of dislike. Actual vomiting, sometimes caused by, again without, cough, may make alimentation difficult. We are however confronted with a simple self-evident proposition. The fire cannot be kept burning without fuel. Patience, firmness and sympathetic reasoning will generally carry the day. The doctor must stand his ground. He should use caution in stating his terms, but he dare not recede from his position or accept any compromise. Much of the ultimate success will depend on the patient's recognition of the necessity for obedience, of his willingness to execute literally the details of the treatment. The greater success of treatment in sanatoria doubtless depends on the influence of example in securing uniform adhesion to established rules. The older patients, those longer in the service, always carry along the new arrivals.

In private practice the task is more difficult, but not to be shirked on that account. Frequently the feeding must be forced at the outset and many dyspeptic symptoms, real or fancied, offer difficulties. The best plan would seem to be to disregard these entirely and continue the feeding. The appetite will grow with what it feeds upon. Three full meals daily should be required. If no gastric symptoms are present and the appetite returns, a sandwich or cracker may be taken between meals. The egg treatment, suggested by Dr. Ely of Rochester, would seem to have a place in the few cases when other foods cannot be taken. Raw eggs are given in steadily increasing number until as many as two dozen are consumed daily.

The effort of the physician is always directed to securing an amount of assimilation in excess of the waste of tissue. Any craving for plain, wholesome, easily digested foods, or for fruits should be indulged; and, contrary to the plan for healthy individuals, the patient should be steadily encouraged to eat more than he wants. Cream and butter should be introduced into as many dishes as possible. Buttermilk and koumyss make acceptable beverages, particularly where fever is present. Albumen water, flavored with lemon, orange or pineapple juice may be substituted for the raw eggs. Concentrated soups, thickened with rice, barley, farina or sago, having an egg or two stirred through each cup, should be taken daily.

Finely scraped raw beef, served with salt and pepper, or covered with a layer of grated chocolate, will be taken when cooked meats are objected to. Game of all kinds may be allowed. Of questionable propriety is the use of pastries, sweets or stimulants, including under stimulants coffee, tea and alcohol. As a general practice they should be omitted from the dietary. The object always is to crowd the nourishment, keeping watch over the digestion, so as not to cause the patient to rebel. The more promptly he grows accustomed to the outdoor life, the better the appetite, and the greater the power of assimilation.

The third feature is good rest. Exercise means tissue waste. The thrifty man of business so arranges his affairs that the income shall more than meet expenses and his constant effort is to curtail the expenses. The poor consumptive has a hard time of it, trying to maintain a balance between income and expense account of his nutrition. He, too, must curtail expenses

where possible and the readiest method is to avoid every effort. He must rest, in the day on a reclining chair or couch in the open air, at night in his bed.

It has been thought a wise plan, particularly at high altitudes, to urge exercise in the open air; camp-life, good enough in itself, but likely to be attended with many needless hardships, not necessarily severe, but always excessive for the sick man; cow-boy life on a ranch; mountain climbing, etc., etc. All of these have their advantages, when the sick man is no longer sick, but while he is sick he must rest, absolutely, continuously and cheerfully. The rule in the Nordrach Sanatorium is that the temperature shall be taken four times daily and the patient gets no exercise until there is no fever. Absolute rest means mental rest as well as physical; this rule is so strictly enforced at Nordrach that patients go to no entertainments, receive no visits, and have their telegrams and letters passed upon by the director; so that no unwelcome, disturbing or exciting news may reach them. This is perhaps an extreme position, but we play for a high stake in this game and every factor counts. The family as well as the patient must be advised and cautioned to eliminate all sources of excitement and worry. The patient should be allowed to sleep as much as he chooses, being awakened only for meals. The excellent results obtained by Trudeau at the Saranac Sanatorium are due in no little degree to the recognition of the importance of absolute rest in connection with other features of the treatment. With a perfectly normal temperature the patient may take a short walk, the thermometer being used after the exercise. If there be return of fever, the walk is either not repeated or greatly shortened. If the temperature remains normal, exercise may be made a part of the daily program, always being controlled by frequent use of the thermometer. The patient cannot rest too much in the early part of the treatment.

Our fourth factor is good cheer. The moral influences surrounding the patient are all important. The text-books dwell upon the familiar "spes phthisica," the pathetic hopefulness of the consumptive, contrasting so sadly with the evident approach of death, of which he alone remains unconscious. It is a frequent occurrence, but the opposite mental attitude, that of resigned indifference, is not less common. Many victims discuss their condition with a certain uncomplaining hopelessness, the conviction of the fatalist, that what must be, must be, and so any positive effort to improve the condition is useless. "Kismet."

The sick man requires constant encouragement from physician and friends. There should be no manifestations of sympathy, but all conversation should be based on the premise of final recovery. The hope of achieving such result must be held out as an incentive to rigid adhesion to the prescribed rules. It is here that the physician meets with grave obstacles. The patient may be ever so willing and conscientious, the design is thwarted by interference of well-meaning, but misguided friends and relatives. The physician must have faith in his own advice, for there can be no works without faith, and he must be able to impress his earnestness upon the patient and his immediate surroundings. Here again the sanatorium has a great advantage of controlling the surroundings of the patient. The beginning of the treatment is the most difficult; once started in the proper direction, the patient improves so manifestly that the task becomes easy. It should be explained to the patient that indulgence in petulance or fits of anger is a serious drawback and delays recovery; and to the family that a little care and thoughtfulness on their part will avoid needless friction.

But what of medicines? Medicines from the shop really do not enter as a necessary part into this plan of treatment. Many cases have so far recovered as to be able to resume work without any medicine. It may serve a certain purpose to give some simple tonic. Creosote in small doses or the bitter tonics can thus be employed. For the night-sweats, a pill of agaricin, gr. 1/6, and atropine, gr. 1/96, may be given at bedtime. A sponge bath of vinegar and water, mixed in equal parts, given at bedtime may control the night-sweats without special medication. If cough or pain be very severe the new derivatives of morphine, dionin, gr. 1/6-1/3, or heroin, gr. 1/12-1/24, will be found very serviceable. Diarrhea, if not dependent upon tubercular ulceration of the intestines, may be checked by the use of bensozol and codeine, or by opium and its derivatives. Many of these annoying symptoms will soon disappear under the general régime without medication; or, if remedies are necessary at the outset, the medicine may soon be discontinued.

The patient, whether married or single, should occupy his or her own bedroom. Sputum should be received in a vessel containing disinfectant solution of some kind and should be emptied into the drains, if in a large city, or preferably burnt. Underclothing worn during the day should be changed at night. The bowels should be evacuated daily. The patient can easily be instructed to keep his own temperature chart. Where practicable, the weight should be taken every two weeks. It is wonderfully encouraging to the patient to note the decline in temperature and the gain in weight. For obvious reasons the tuberculous patient should not marry, a caution which, especially for female patients, is not as superfluous as it may seem. Pregnancy, with its demands on the mother's nutrition, is a most unfortunate complication; it often renders the condition hopeless for the mother. The child is generally carried to term, but the mother does not rally from the puerperal period and her decline is then very rapid.

What cases are especially suitable for this home treatment? All cases are suitable, even the most desperate. In Nordrach no case is re-

fused because of the advanced stage of the process, and all are treated by the same method. Naturally the best results may be anticipated when the disease is recognized in its incipiency; so that destructive changes over large areas may be prevented; but no case short of being actually moribund need be denied a trial of the method. One case of my own, a young man of twenty-two, whose unusual mechanical talent and great industry made him foreman of a large machine-shop before his twenty-first year, had an attack of pleurisy a year ago, tuberculous pleurisy, doubtless, which left the right lung compressed into the apex of the chest-cavity. At Christmas he had repeated hemorrhages for two weeks. I saw him for the first time early in January. The air-containing space of the right lung was now converted into a cavity, and there was some infiltration at the apex of the left upper lobe. He was coughing constantly, so that he could not sleep; the cough induced vomiting; his night-sweats were very profuse and his temperature was constantly above normal. His home is on one of the hillsides overlooking the valley in which our city lies. Three weeks of open-air treatment wrought a wonderful change; he slept through the entire night; the expectoration which, at the first test, contained bacilli in great abundance, was now reduced to less than half the former quantity; night-sweats had ceased; the fever amounted only to a slight evening elevation; vomiting no longer occurred, the appetite had returned and there was a manifest improvement in strength, color and spirits.[1]

It is upon the general improvement, rather than upon disappearance of bacilli from the sputum, that reliance is mainly to be placed. Experience has shown that tuberculous areas are not destroyed under this plan, though it would seem to favor that process of fibrous inclusion by which extension of the morbid process is arrested; thus following the method of spontaneous cure which Nature, as autopsies prove, accomplishes unaided in many instances. In some cases patients, so far restored as to be able to resume work, have continued to expectorate tubercle bacilli.

There is no worthier cause to which the profession can earnestly devote itself than the care of patients suffering from this disease; there is none in which the results are likely to yield more encouragement to the patient and inmost satisfaction to the physician. Recovery cannot be expected in every case; but it is fair to speak of recovery where the wage-earning capacity of the sufferer is restored, and improvement to this degree may be confidently expected in a number of cases hitherto regarded as condemned without hope.

1105 McMillan Street.

[1] Four months have passed since the above was written. The young man is now making models for machinery in a small laboratory in his own home. He climbs the surrounding hills without effort or dyspnea and has gained twenty pounds in weight. No air enters the right lung. The infiltration at the apex has disappeared.

IRITIS.[1]

By J. H McCASSY, M.A., M.D.,
OF DAYTON, OHIO.

The iris is the colored membrane which separates the lens and its capsule from the cornea. It floats in the aqueous humor and divides the aqueous chamber into two parts. The anterior chamber is the larger of the two. These two spaces communicate through the pupil. The iris is the only muscular organ that is constantly immersed in liquid.

A more or less constant relation exists between the pigmentation of the cutaneous structures and that of the iris. Blondes will have light and brunettes dark colored irides. To this rule numerous and important exceptions occur. Blue and gray are the predominating colors in the irides of the inhabitants of northern countries. Brown comes next in frequency and this is the prevailing color found in tropical and semitropical countries. Brown being a dense pigment it more nearly excludes the brilliant light found in southern lands. Perfectly black irides are never found. With few exceptions the color of the iris in new-born children is of a light grayish-blue. The stromal pigment, which is the final fixed color of the iris, is not developed until after the third month. Mothers anxiously watch these changes. If the color of the irides of the parents differ, Nature occasionally tries to please both by blending the colors.

In many cases the pigment may not be evenly distributed in the same eye, and unless this fact is known the densely pigmented patch may be mistaken for an old iritic patch. We also find a difference in the color of the two irides; one may be brown, the other blue or gray. It is said that in cases of chromatic asymmetry there is great liability to cataract in the lighter colored eye. Where both irides are known to be of the same color prior to a painful disease of the eye, and upon inspection in after years it is found that in one eye the iris is blue or gray while the other is greenish or brown, this will be evidence of an old iritis or cyclitis. A blue or gray iris appears greenish in iritis while a brown iris appears muddy.

The pupil, the circular opening in the iris, should measure about 4.14 mm. or one-fifth of an inch in diameter. The size of the pupil is influenced by many conditions. It is smaller in old age, in blue eyes, and in hypermetropes; larger in youth, in dark eyes, and in myopes. Contrary to the current notion, the pupil is not in the center of the iris, but a little to the nasal side. The pupil, or rather the pupillary margin of the iris, should be freely mobile. If it is not, it may be attached anteriorly to the cornea or posteriorly to the lens capsule. These attachments are designated anterior and posterior synechiæ respectively.

[1] Read before the Montgomery County Medical Society, May 4, 1900.

Causation.—Iritis furnishes from 3 to 4 per cent. of all ophthalmic cases. When allowed to run its course it is one of the most fatal diseases to sight. In this disease above all others prompt medication has its highest achievements. Medication here is equivalent to a prompt, brilliant surgical operation. Iritis is most amenable to prompt treatment. It occurs most frequently between the twentieth and fortieth year. It is not very frequent during the first fifteen years of life and during old age. It affects men more frequently than women. Syphilis is responsible for 60 per cent. of cases. Rheumatism (articular) causes 10 to 20 per cent. of cases, the remainder being due to various causes such as injury, gonorrhea, gout, diabetes, malaria, etc.

Varieties.—(1) Plastic; (2) serous; (3) parenchymatous. Plastic iritis is by far the most frequent variety met with and is characterized by pericorneal congestion of a grade in proportion to the severity of the disease. As seen by oblique illumination, there is an exudate of organized lymph on the surfaces of the iris. This is very prone to form adhesions. The aqueous humor is not greatly clouded, and the cornea is not spotted. The pain is more intense in this than in the other varieties. The pupil is sluggish and contracted and stubbornly resists the action of mydriatics.

In the second variety the exudate instead of being plastic is serous in character and contains solid elements which usually become deposited in spots on the posterior surface of the cornea. The aqueous is very murky and cloudy. The pupil is not contracted but may be slightly dilated. The tension is often increased, due perhaps to the increased secretion of the aqueous humor or blocking of the entrance to the canal of Schlemm with exudate. As a rule hypopyon is absent. Opacities in the vitreous body are very common. Serous iritis is prone to glaucoma and here atropine should be used with great caution. Paracentesis of the cornea may be repeated to keep down high tension or an iridectomy may be made to avert glaucoma.

In parenchymatous iritis or suppurative iritis, the inflammation attacks the tissue of the iris and instead of the exudate being on the surface of the iris, it is found within. This gives to the iris its characteristic swollen and nodular appearance. The surface appears spongy. This exudate may be extensive. It may suppurate and fall to the bottom of the aqueous chamber in a thick mass known by the name of hypopyon. The hypopyon may undergo absorption in a few hours or in a few days.

Symptoms.—Pain, not so much in the eyeball as in the brow, temple and cheek. Photophobia, lachrymation, pericorneal redness, impaired mobility of the iris, exudation of inflammatory products, and disturbance of sight. These symptoms are common to all forms and types of iritis, and it is not so important to know which form of iritis you have to deal with as it is to be sure you have iritis and not conjunctivitis or glaucoma.

Diagnosis.—Iritis is so intimately associated with cylitis and the treatment practically the same, that it is not necessary at this time to differentiate one from the other. Iritis may be mistaken for conjunctivitis or acute glaucoma. To treat an iritis for conjunctivitis, delaying the use of atropine, the sheet anchor in the former, is a disastrous mistake, but as lamentable as this may be it is still worse to treat acute glaucoma for iritis. The treatment for iritis is most emphatically contraindicated in any form of glaucoma.

In iritis there is found: Hyperemia of the iris; aqueous murky and turbid; iris thick and swollen; pupil contracted and immobile; pain on exposure to light; synechiæ posterior (adhesions); tenderness on pressure; sclerocorneal rosy zone; punctate spots on the cornea; occasional edema and ptosis of upper eyelid; tension slightly increased; hypopyon occasionally; no conjunctival secretion; free lachrymation; vision affected; severe pain in the brow and temple, intermittent or neuralgic in character.

In conjunctivitis there is found: Iris has natural appearance; aqueous clear; no swelling of the iris; movements of the iris free; no dread of light; no exudate nor adhesions; very slight tenderness; uniform conjunctival redness; cornea clear; moderate edema; no increase of tension; never hypopyon; abundant secretion gluing lids together; copious lachrymation mixed with pus or muco-pus; vision unaffected; sandy scratchy sensation in the eye continuously.

It is always difficult to diagnose glaucoma in the early stages. The diagnosis hinges on the tension of the eyeball, and this is always difficult to determine. In acute primary glaucoma (inflammatory), as in iritis, there is pain, photophobia, lachrymation, redness of the sclera and redness of the lids and disturbance of vision. The pupil reacts sluggishly and the iris is discolored. To determine the presence of glaucoma one has to depend on the dilated pupil, severe pain in glaucoma and high tension. Later on the ophthalmoscope will reveal abnormal cupping or excavation of the optic nerve which usually begins on the nasal side.

In order to distinguish rheumatic from syphilitic iritis the following points will be noted. In rheumatic iritis the following symptoms are present: History of articular rheumatism; pain, photophobia, and lachrymation marked; condylomata never observed; exudative changes slight; posterior synechiæ long, thin and non-pigmented; iris often strikingly bright; no pigment spots on anterior lens capsule; not associated with choriodoretinitis; generally perfect recovery of sight; great tendency to relapse; whereas in syphilitic iritis the symptoms are as follows: History of acquired syphilis; pain, photophobia and lachrymation not equally well marked; condylomata present in nearly all cases; extensive

exudative changes; posterior synechiæ short and deeply pigmented; iris often dull and muddy; abundant pigment in anterior lens capsule; choriodoretinitis and blurring of optical disk; sight often impaired; much less tendency to relapse.

Duration.—Iritis or cyclitis may be acute, subacute or chronic. Acute iritis speedily reaches its height and in rare cases runs its course in one week, but the usual duration of acute cases is four to eight weeks, while chronic cases last for months.

Pathological Anatomy.—In diseases of the blood-vessels, due to infection, particularly syphilis, there is a plastic exudation thrown out together with a cellular hypertrophy of the tunica media. This means loss of elasticity and contractility. This new material thrown out is a low grade of tissue, weak in its powers of resistance, and is a favorable site for disease. Where seclusion of the pupil has occurred, atrophy of the iris will take place along the pupillary margin. If the entire posterior surface is adherent, and remains so, sooner or later atrophy of the whole iris will take place. When the undilated iris becomes permanently adherent to the lens capsule around its entire pupillary margin, we have a condition known as seclusion of the pupil. This leads to glaucoma and destruction of the eye, because there is no longer any communication from the anterior to the posterior aqueous chamber.

Occlusion of the pupil differs from seclusion of the pupil in that the communication between the two chambers is not cut off, but the pupil is closed by a diaphragm or membrane formed from the exudate thrown into the pupil. Occasionally, during an attack of iritis the tissues of the eyeball are put upon the stretch and the eyeball becomes elongated or the inflammation may cause spasm of the ciliary muscle. The lens may become thicker or advance. These conditions will change a far-sighted eye to a near-sighted one, but when the iritis passes away, the eye generally returns to its former state of refraction.

Prognosis.—If the pupillary attachments refuse to be broken up, no matter how successful the constitutional medication may be, the future of that eye will be uncertain. Such an eye cannot stand strain and exposure. It is weakened and liable to recurrent iritis and sympathetic ophthalmia. If free dilation of the pupil can be secured and the injury has not been too great, the prognosis is favorable.

Treatment.—Atropine is the sheet-anchor in iritis. It is the great anodyne. It paralyzes the sphincter muscle and puts at rest the mobility of the pupil, breaks up adhesions and puts the pupil back out of the way. Adhesions are not so likely to occur when the pupil is widely dilated. A solution of sulphate of atropine, four grains to the ounce, instilled every hour or two for eight to twelve hours if necessary until the pupil is fully dilated. Then one drop every four hours will usually be sufficient. If poisonous symptoms appear atropine must be stopped for a few days. A calomel purge followed by a saline acts like a charm in iritis. This, with hot baths, lowers the tension of the eyeball.

An inflamed and watery eye with impeded circulation does not present a good surface for absorption, but the application to the eyelids and brow of hot, wet cotton or towels changed every minute will promote circulation, increase absorption of the atropine or other mydriatic, and relieve pain. Smoked glasses screen the eyes from the harsh rays of light and afford more suitable protection than bandaging. If a broken or swollen lens is the cause of the iritis it should be removed; three or four leeches applied to the temple, forehead and side of the nose are very beneficial. The artificial leech may be used, but it has been unsatisfactory in many hands. Morphine, Dover's powder or aconite may be used to combat pain. Both eyes should be allowed to rest. There is no such thing as resting one eye by closing or bandaging it while the other is at work. The too early use of the eyes will cause relapses. For syphilitic iritis, mercury is the remedy. This should be followed by iodide of potassium. The salicylate of sodium and the alkaline carbonates are the mainstay in rheumatic iritis.

Surgical Treatment.—Paracentesis is indicated when the tension of the eyeball is persistently and notably raised; also in large hypopyon or dotted spots upon the back of the cornea, or, when the inflammation refuses to yield to milder means. In seclusion or occlusion of the pupil an iridectomy should be performed as soon as the disease becomes quiescent.

CLINICAL MEMORANDUM.

MERALGIA PARESTHETICA.

By JAMES J. WALSH, Ph.D., M.D.,
OF NEW YORK;
INSTRUCTOR IN CLINICAL MEDICINE IN THE NEW YORK POLYCLINIC HOSPITAL AND SCHOOL FOR GRADUATES IN MEDICINE.

Altogether about a hundred cases of meralgia paresthetica have been reported by various observers. Drs. Musser and Sailer recently collected from literature some eighty-nine cases of the disease to which they added ten of their own.[1] It is only six years ago that the first case of the disease was reported. Bernhardt, who reported the case, had observed the condition some years before in another patient, but did not consider it of sufficient importance to deserve special mention. Other observers, including Musser and Sailer in this country, had observed cases of the affection before Bernhardt called attention to its independent character. A few months after Bernhardt's article Roth published reports

of fifteen cases of the disease. It is interesting to note that of the hundred cases reported about ten per cent. occurred in physicians. There is every probability that the affection is much more common than it might be thought to be from the recency of its introduction to medical literature as a distinct nosological entity. Notwithstanding this there are excellent observers who have been very carefully on the lookout for cases in recent years, yet have seen none. It seems worth the while therefore to report a case that has recently been under observation in Professor Katzenbach's clinic at the New York Polyclinic and which seems to respond very well to the definition of meralgia paresthetica given by Musser and Sailer, *viz.*: "A disturbance of sensation on the external surface of the thigh characterized by various forms of paresthesia accompanied by dissociation and more or less diminution of sensation."

It was in 1895 that Bernhardt[2] described a series of cases all of which were distinguished by the presence of a disturbance of sensation in a smaller or larger area on the outer side of the thigh. Bernhardt is an extremely acute observer. His work in recent years on peripheral nervous diseases has led him to the discovery of a number of symptom-complexes the independent character of which was not realized before. For these he has usually been satisfied to describe the symptoms and point out their coincidence in a series of cases, leaving the naming of the affection to others. The names selected have in at least one other instance besides our present subject been striking. It was Bernhardt[3] who first described the peculiar ache which occurs in the muscles attached to the external condyle as the result of strain or overexertion. The condition is noted in neurotic people who carry a heavy umbrella for a long period or make some other unusual exertion involving these muscles. To this symptom-complex French neurologists gave the name epicondylalgia. The baptism of the sensory symptom-complex on the outside of the thigh was left to a Russian. Roth of Moscow describes fifteen cases of the affection and gave it the impressive name meralgia paresthetica. From the high-sounding title one might be led to expect much of the disease. It really consists of nothing but a painful patch of skin on the outer part of the thigh. It is usually mistaken for rheumatism and our case has been treated as such for a long while. As there is no treatment known that accomplishes any real good in the affection no harm is done in treating it as rheumatism. It might as well be treated by rheumatic remedies as anything else.

The patient was a Polish Jew, about forty-five years of age, who complained of painful, at times hot, feelings on the outer part of his right thigh. Examination showed that besides these subjective symptoms there were certain objective symptoms. An oval patch of the cutaneous surface, about five inches long by about three inches wide, was almost anesthetic when pricked with a pin point. The area of anesthesia was not abruptly defined, but shaded off gradually into the surrounding normally sensitive tissue. In a corresponding area on the left leg there was a patch of slight hyperesthesia. No complaint of pain was made as to this left lateral region and the patient knew nothing of the existence of any symptoms on what he considered his well side until they were demonstrated during the examination. There was some dissociation of sensibility over the area complained of as painful. The man was a cabinet-maker and had to be on his feet most of the day. He used a plane a good deal and his right thigh was constantly rubbed during his work against the side of the work-bench on which the planing was done. It always gave him ease to sit down and his pain completely disappeared on lying down. More discomfort was felt just before a rain-storm than at other times. As soon as rain actually began to fall, however, the discomfort became less marked.

The patient was a neurotic individual with a tendency to neurasthenic symptoms and to general exaggeration of any pains and aches that he had. His knee-jerks were slightly exaggerated. He was inclined to constipation and had evidently suffered for some time from a certain amount of gastrointestinal disturbance. He had been recommended to apply iodine externally and to rub the affected area with chloroform-liniment. Both of these remedies made the condition worse instead of better. He had been treated with the ordinary rheumatic remedies, the salicylates, for a long time, but without relief. The administration of a stimulant nervous tonic seemed to do him some good. Rubbing with simple soap-liniment apparently gave him more relief than any other remedy that had been employed. Perhaps because of this, or because the coming of milder weather brought relief, he passed from observation early in the spring.

It was difficult to find out just when the affection began. When the patient first came under observation in January it had existed for several years, always being worse in the winter time. There was no history of alcoholism in the case, specific infection was denied and there was no good reason to doubt the denial. There was no history of any direct trauma. This part of his leg was, as has been said, continually pressed against the planing-table and this perhaps had something to do with the development of the painful condition. The corresponding patch of hyperesthesia on the other thigh seemed to indicate that another area of paresthetic meralgia was already in process of development on that side.

In most of the reported cases the affection had been symmetrical. For the area of disturbed sensation on the left thigh there was no special feature of his daily occupation that might be considered as an etiological factor. It is probable that the case was one of true meralgia par-

esthetica due, as are most of the other cases of the affection in medical literature, to a neurosis, that is, to a functional disorder of a localized part of the central nervous system. As is pointed out in the article by Musser and Sailer, the affection resembles an occupation neurosis more than anything else. It is true none of the ordinary occupation neuroses are limited to the distribution of a single nerve, as is the case in meralgia paresthetica. It would seem, however, that the true explanation of the affection will come with advance in our knowledge of the neurotic manifestations due to various occupations which have attracted so much attention of late years.

MEDICAL PROGRESS.

The Liver and Nephritis.—Digestion, nutrition and elimination constitute the normal metabolic processes of the human organism and in the maintenance of these natural functions of animal life the liver plays a most essential part. It is the most important organ of digestion, says G. E. Davis (*Med. Rec.*, September 15, 1900) not only on account of its biliary function in preparing fats for absorption and digestion, but also because of the secondary digestion and elaboration of food products which fall on the liver after these materials have been absorbed into the portal system. It may also be considered the most important eliminative organ in the body, not simply through the bile excretion, but on account of its capacity of transforming the products of disintegration and completing the retrograde changes from non-diffusible colloids into crystalloid diffusible materials before they pass to the kidneys for final excretion. Many investigations have proven the intimate relation between the liver and kidneys. Urea is formed by the liver and returned to the blood to be excreted by the kidneys, and hence an analysis of urine is a good test of the hepatic activity. Renal insufficiency, therefore, proclaims preceding hepatic insufficiency—disturbed nutrition and autointoxication intervening. The kidneys first suffer functional disturbance because the imperfect products are brought to them in a form chemically unable to pass through them, organic change supervening as a result of long-continued irritation occasioned by these incompleted products of metabolism. The indications for treatment, then, in derangements of the kidneys are to aid digestion and nutrition and promote disintegration. Regulation of diet and fresh air are important. Then come the cholagogues and alteratives and often the best diuretic is the drug which arouses the hepatic functions.

Erosions of the Stomach.—The distinction between ulcer and erosion of the stomach mucous membrane was first made by Dr. Einhorn only a few years ago, and even now the differential and diagnostic points of the two considerations are appreciated only by a few. E. Quintard (*Med. Rec.*, September 15, 1900) has reviewed the literature on the subject, showing how the two classes of cases have been confused. By an erosion he means a superficial solution of continuity in the gastric mucous membrane, never extending so deep as the submucosa and the edges of which never present the indurated margins of the peptic or round ulcer. This does not mean necessarily, however, that there are two different processes pathologically. There was loss of flesh, the pain after eating was not very intense, there was considerable exhaustion after exertion, a pinched and haggard look at times, and, finally, that which made the diagnosis positive, the repeated findings in the wash-water of little pieces of gastric mucosa. As far as treatment is concerned, it would seem that excellent results are to be had from the use of a silver nitrate solution, 1-500, sprayed into the stomach by means of an Einhorn atomizer when the stomach is in a fasting condition. After two or three such applications at intervals of two days, the fragments usually cease to appear and the subjective symptoms clear up with a general improvement in the patient. Einhorn has recently used five grains of suprarenal extract for powdering the stomach in these cases with good results. The conclusions are that there are patients who give a peculiar and definite clinical history distinct from that of round ulcer, in whose stomach-washings are repeatedly found small fragments of mucous membrane, varying from 2 to 7 cm. long. They form a distinct class clinically and should be treated as such, but they occur under varying pathological conditions and, hence, the functional signs vary accordingly. As far as the presence of hydrochloric acid is concerned, it may be increased, normal, or much diminished.

Tuberculosis in Infant of Fifty-Six Days.—Any new report of a case of tuberculosis in very early life is always sure to incite new interest in the subject of hereditary transmission of the disease. The infrequency of the disease is well shown by the figures given by J. Comby (*Archives de Médecine des Enfants*, September, 1900) who adds another case to the list. Among 118 autopsied infants from birth to three months of age only one case of tuberculosis was observed, less than 1 per cent.; on the other hand this percentage rapidly increases with the increase in age. The case reported by the writer was that of a male infant, admitted to the Hôpital des Enfants-Malades in Paris, one month old. The mother was tuberculous, the father apparently robust. The child had been nursed by the mother for three weeks, then given boiled cow's milk. When admitted to the hospital the patient was suffer-

ing from gastroenteritis which persisted until death. The autopsy findings showed tuberculosis of the spleen, with advanced tuberculous lesions in the lungs. Comby expresses the belief that this is an example of inhalation tuberculosis in infancy; he sees no evidences of a congenital origin of the disease.

New Technic for Staining Tubercle Bacillus.—Such a variety of staining methods for the bacillus of tuberculosis is in vogue that the selection of any method necessarily depends largely on questions of certainty, adaptation, and preference. In a recent paper Dr. Randle C. Rosenberger (*Journal of Applied Microscopy*, June, 1900) has discussed several of these stains in the light of his own experience. The almost universally employed carbol fuchsin stain, as recommended by Ziehl and Neelsen, is one of the best methods. The method brought forward by Marion Dorset, who claims to have obtained a very good result when spreads were first stained with an alcoholic solution of Sudan III and then decolorized with dilute alcohol, 70 per cent., has been found to be most uncertain, because of the different makes of the stain. Anilin gentian violet is another very good stain, and when a specimen is stained with it, then decolorized with a twenty-five-per-cent. solution of H_2SO_4 and counterstained with vesuvin, a very good picture is obtained. The author believes that most people make the spread entirely too thin; he advocates having a good layer of the material to stain. The method practically recommended is one devised by Rosenberger and used by him for some time with gratifying and reliable results. The essential feature of his method consists in the substitution of sweet spirits of niter as the bleaching agent instead of the sulphuric or nitric acids habitually used. Further, the writer has combined the sweet spirits of niter and methylene blue with malachite green, Bismarck brown, and gentian violet. In this method the preparation is first stained with carbol fuchsin for five or ten minutes; then the mixture is placed upon the spread, after washing off excess of carbol fuchsin for one or two minutes and washed with water. If a green or blue color is not present, place the solution on again and wash with water. In specimens of urine where so much granular debris is present, and in some specimens of old sputum, this method is particularly applicable. The reason is that the niter dissolves out all fatty, granular particles and leaves a clean cut, well-defined field behind. The smegma bacillus is also decolorized with this stain. Where the sweet spirits of niter and the malachite green mixture is used, a beautiful contrast stain is obtained, green being the complementary color of red. In making up the mixture enough of the stain, malachite green or methylene blue in fifty-per-cent. dilute or saturated alcoholic solution is added to the niter to make a deep-green or blue fluid; the same with Bismarck brown. Tubercle bacilli in tissues may be stained by this method, a longer application of the counterstain (five minutes) being needed, however. The specimen is then washed in water, *nearly* dried, and placed in carbol xylol to clear, and finally mounted in xylol balsam. The bacilli are stained red, the tissue a brown, blue, or green, according to the stain used. The advantages claimed for this method are (1) that it is easy to prepare; (2) that it gives a clearer, better defined field; (3) that it does not destroy the tissue, as is sometimes the case with H_2SO_4; (4) that it acts more quickly and surely; (5) that it keeps indefinitely.

Pneumonia Following Laparotomy.—G. Kelling (*Münch. med. Woch.*, August 21, 1900) has often seen pneumonia after abdominal operations, especially those on the stomach, and classifies its etiology as follows: (1) By aspiration during narcosis. (2) By embolism from the ligated vessels, the emboli reaching the lungs through the anastomosis between the gastric and esophageal vessels. (3) By hypostasis. (4) As a result of an epidemic. The prevention will depend on the cause. Where congestion of the dependent portions of the lung is feared the bandage should be applied so that breathing is interfered with as little as possible, the patient should be allowed to sit up after twenty-four hours and exercises his lungs, and digitalis should be given. As far as the embolic form is concerned it is necessary to prevent as much as possible the mechanical aspiration of air into the peritoneal cavity during the respiratory movements and have the air itself pure and free from germs. Since the author has become cognizant of these facts he has built a new operating-room, with improved ventilation, with the gratifying result of not a single pneumonia in twenty abdominal operations.

Pulmonary Tuberculosis and Injection of Nitrogen.—The idea of injecting some gas into the pleural cavity was suggested as a result of the improvement which was observed in other tuberculous lesions when complete rest had been enforced for some time, and furthermore the well marked amelioration of symptoms which had been noticed in several cases following the accidental formation of a pneumothorax was most suggestive and significant. Dr. Murphy of Chicago was the first to urge this method upon the profession of this country and only a few have made any extended experiments to prove its efficacy. H. P. Loomis (*Med. Rec.*, September 29, 1900) reports the results of this form of treatment which he has tried upon eighteen selected cases during the past two years. It is necessary to make sure that the nitrogen is pure and a special apparatus as recommended by Dr. Murphy is most advisable. The gas is usually injected in the eighth interspace unless the lesion is in the lower lobe, when it should be injected in the third or fourth space anteriorly. When many adhesions are present several trials may be necessary or injection may be entirely impos-

sible. One hundred or more cubic inches of gas are usually employed and this amount generally causes a disappearance of all respiratory sounds and considerable displacement of the heart. Permanent beneficial results necessitate that the lungs be kept quiescent for from three to six months, two or three injections usually being sufficient for this period. A constant effect noted after the operation is that there will be a marked increase in the expectoration during the first twenty-four hours, but after a few days this rapidly diminishes. The gain in weight is very constant and even astonishing in amount. Nearly all subjective symptoms are markedly improved but the physical signs do not seem to be much altered. Several cases of persistently recurring hemoptyses were entirely stopped by injections and the author is thoroughly convinced of the efficacy of this method in early cases, with distressing hemorrhages. The best results can be expected from cases of apical unilobar tuberculosis without adhesions, in which the most compression can be obtained. Even the advanced and apparently hopeless cases can, however, be relieved of many of their distressing symptoms, unless the number of adhesions prevents the collapse of the lung. A more extended use of this method is strongly advised, for no bad results or even unpleasant effects have yet been detected. An apparent complete arrest of the disease has been noted in two cases and nearly all have shown decided constitutional improvement. A marked gain in weight has been seen in every case, even in those where the patient had previously been rapidly losing. It is believed that this method of treatment will have a permanent place in the amelioration of the symptoms of pulmonary tuberculosis and it is to be hoped that it will be given a more extended use in order that the kind of cases to which it may be best applied can be ascertained.

Therapy of Iodipin.—According to B. Sessous (*Münch. med. Woch.*, August 21, 1900) there are three convenient methods of giving iodipin. It can be given by mouth in the form of a preparation containing 10 per cent. iodine which allows the detection of iodine in the saliva after as short a period as 10 to 15 minutes; it may be injected subcutaneously, when its action is less rapid although more persistent and finally inunctions may be given, with however less satisfactory results. Iodipin finds its greatest field of usefulness in those forms of tertiary syphilis where the iodides, on account of gastric or other disturbance, are contraindicated. There is as yet a great diversity of opinion as to the size of the proper dose, some advising small, others large doses, but even the largest that it has been customary to give but rarely cause symptoms of iodism. The increase of peristalsis which is sometimes seen can only be regarded as desirable and is due to the fatty nature of the drug. Its use in bronchial asthma and in emphysema also affords advantage.

Stricture of the Esophagus.—While the diagnosis of this condition is usually to be easily and satisfactorily made by means of the esophageal bougie, the use of this instrument is sometimes inadmissible owing to suspected aneurism of the aorta, hematemesis, the weakness or disinclination of the patient, etc. Under such conditions a method described by Holzknecht (*Deutsch. med. Woch.*, September 6, 1900) is likely to be of great value as it gives accurate information regarding the presence, locality, caliber and length of a possible stricture in a simple and painless way that is free from all risk. On illumination of the chest by means of an X-ray tube placed below the right shoulder and with the fluorescent screen arranged so that the line of sight runs from the left behind, forward and to the right the esophagus is visible as a light streak occupying the position between the dark masses of the heart and the vertebral column. On giving the patient a small quantity of water holding in suspension 15-30 grs. of subnitrate of bismuth, if a stricture be present, the fluid will be arrested at this point and a precipitation of the metallic powder takes place which will throw an appreciable shadow on the screen. This test is mainly useful in stenoses of small caliber and if it prove negative the bismuth should be enclosed in a capsule and the process of deglutition observed as before. If this, too, fails it may be well to repeat the experiment having preceded the administration of the capsule by the giving of a small morsel of bread which is sure to be arrested and so impede the progress of the test object.

Cerebral Abscess Secondary to Typhoid.—A. C. Brown (*Edinb. Med. Jour.*, September, 1900) reports a case which is interesting on account of its etiology, the difficulties in the way of diagnosis and the success of the treatment. No instance has yet been recorded in which pyogenic organisms gaining access to the circulation from the intestinal ulcerations of typhoid have been deposited in the brain with the production of a suppurative focus. In this case the patient, a girl of nineteen, developed the symptoms of Jacksonian epilepsy shortly after discharge from the hospital, where she had been treated for a moderately severe attack of typhoid fever. The nervous disturbances were purely motor in character, sensory symptoms and cerebral derangement being entirely absent so that the focal lesion could be definitely located in the right Rolandic area, as the convulsions affected the left arm and leg. The nature of the lesion was more difficult to determine, functional disturbance of the cerebral centers, abscess, tubercle and syphilis were one by one considered and rejected. Against abscess were the position of the lesion, the absence of any exciting cause or rise of temperature (a blood examination was not made), and a provisional diagnosis of a rapidly growing gliomatous tumor was made. On operation, however, the error was recognized and three ounces of pus evacuated, after which the patient made a complete and uneventful recovery.

THERAPEUTIC HINTS.

Castor Oil.—An easy method of administration is to moisten the glass with whiskey, and then pour into it successively:

Glycerin	ʒiij
Ol. Ricini	ʒss
Tr. Cardam. Comp.	ʒi.

This is to be swallowed without mixing.

Acute Posterior Gonorrhea.—The patient is put to bed on a milk diet, the testicles suspended, and the bowels kept open. Alkaline mineral waters and the following formula are given:

℞	Potass. Bicarb.	ʒi
	Tinct. Hyoscyam.	
	Fl. Ext. Kava Kava, aa.	ʒss
	Aq. q. s. ad.	ʒviii.

M. Sig., ʒss in water two hours after each meal and before sleeping.

Relief is obtained from hot-water bags over bladder and perineum, from rectal injections of hot water, or the hot sitz bath; if the vesical and rectal tenesmus resist this treatment, use morphine suppositories. If retention of urine occurs, throw into the urethra a few drops of four-per-cent. cocaine before attempting catheterization. When the acute symptoms subside resume local urethral treatment and allow the patient up. —*J. R. Hayden, Manual of Venereal Diseases.*

Liquor Acidi Phosphorici Comp.—Under this name the late Wm. Pepper frequently prescribed the following:

℞	Calcium Phosphate	gr. xxiv
	Potassium Phosphate	gr. ij
	Magnesium Phosphate	
	Ferrous Phosphate	aa. gr. iv
	Syrupy Phosphoric Acid	♏ 50
	Water to make	ʒi.

Sig., ʒi t. i. d. after meals for an adult.

Emulsion of Linseed Oil.—In certain pulmonary conditions and as a general nutritive, W. H. Thomson prescribes the following:

℞	Ol. Lini	ʒ xv
	Ol. Gaulther	
	Ol. Cinnam.	aa. ʒij
	Ac. Hydrocyan. dil.	ʒiiss
	Glycerin	ʒv
	Syr. Simpl.	ʒx
	Aquæ	ʒxxiv
	Chondrus	ʒss.

Ft. Emuls. Sig., ʒij-ʒiv t. i. d.

Premature Babies.—At the Sloane Maternity Hospital premature babies are either placed in an incubator, or enveloped in cotton, or surrounded by hot-water bags. At first they are given one-half to one teaspoonful of six-per-cent. sugar-of-milk solution every hour, and this is gradually increased by the addition of breast milk until the latter predominates. To promote sucking at the bottle they are made to cry, or their lips are moistened; if they will not suck they are fed by pipette. Gavage is seldom used as they do not stand it well. Incubator babies are kept in the incubator as long as premature, but the others are put to the breast in from three to ten days. If stimulation is needed, oxygen and brandy, a few drops at a dose, are employed. Modified milk, with fat, 1 per cent., sugar 6 per cent. and proteids, 0.33 per cent., may also be given.

Epidemic Conjunctivitis.—According to Hermann Knapp, in this affection the so-called "pink eye," cleanliness and mild antisepsis are the essentials. Among the solutions which may be used are sodium chloride, 1 to 1000; boric acid, 1 to 4 per cent.; potassium chlorate, ½ to 1 per cent.; corrosive sublimate, 1 to 5000, or silver nitrate 1 to 5000. For immediate relief, ice compresses lessen the inflammation and 4 per cent. cocaine removes the gritty sensation.

Anemia.—The anemia of chronic malarial poisoning is especially improved by iron. If enlargement of the spleen and engorgement of the portal circulation coexist, compound jalap powder should precede the iron; or the latter may be combined with resin of podophyllum, as follows:

℞	Quininæ Sulphat.	ʒi
	Resinæ Podophylli	gr. iv
	Ferri Sulphat. Exsic.	gr. xx.

M. Ft. pil. No. XX. Sig., one or two pills three times a day.—*Bartholow in Materia Medica and Therapeutics.*

Treatment of Corns.

℞	Extract of Cannabis Indica	1
	Salicylic Acid	10
	Oil of Turpentine	5
	Glacial Acetic Acid	2
	Cocaine (Alkaloidal)	2
	Collodion, q. s. ad.	100.

M. Apply a thin coating every night, putting each coating on top of the preceding one, until finally the whole drops off, bringing the indurated portion, and frequently the whole corn with it.

Pulmonary Emphysema.—For twenty days out of each thirty take of potass. iodid., gr. xv., aq., ad ʒi. a teaspoonful at each meal. During the other ten days take a tablespoonful of sodii arseniat., gr. i., aq., ʒviij. Take at bedtime every eighth day a two-grain pill of aloes; avoid tobacco, and drink milk.—*Journal de Médecine, September 9, 1900.*

Eczema of the Scalp.—Joseph Max recommends corrosive sublimate, one grain, in one ounce of vinegar, to kill pediculi and remove the nits. This is used twice on the first day, followed for a few days by acetate of aluminum solution to allay the irritation, and then by the following ointment:

℞	Hydrarg. Sulph. Rub.	gr. v
	Sulphur Sublimat.	gr. xx
	Ol. Bergamot	gr. viij
	Vaselin q. s. ad.	ʒi.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, OCTOBER 6, 1900.

THE BACTERIOLOGY OF THE INTESTINE IN ITS RELATION TO SURGERY.

Few subjects of equal magnitude command more earnest consideration than that of peritoneal infection. In these days when the triumph of highly-developed technic has inspired so many new outlooks in intestinal surgery no subject could possess more fitting interest than the relations of intestinal bacteriology to operative procedures on the stomach and intestines. It has become evident to more than one thoughtful student of surgery that any improvement on the side of infection in this class of cases must be sought for in fuller and more extended studies of the normal and pathological bacteriology of the intestinal tract. An important step which does much to place the whole subject on a more intelligent footing has recently been made by two American investigators, Drs. Cushing and Livingood (Contributions to the Science of Medicine by the pupils of Prof. William H. Welch, 1900), who made an experimental and surgical investigation of the bacteriology of the upper portion of the alimentary canal, with observations on the establishment there of an amicrobic state as a preliminary to operative procedures on the stomach and small intestine.

The investigations of Escherich, Popoff and Szegö have shown that the intestinal tube of infants remains sterile for some hours after birth, the duration of which apparently depends upon the interval elapsing before the earliest nourishment is given. Under ordinary conditions of life micro-organisms make their appearance shortly after birth in all parts of the digestive tract. In many animals the colon bacillus and its near allies seem to be, as in man, the chief obligatory forms. Although the bacterial flora is subject to variations according to the kind of food ingested, Lembke has abundantly demonstrated that the Bacillus coli alone remains constant and independent of diet. Aside from this ever-presiding organism and possibly one or two other forms which Macfayden and Ciechomski have found to be present with some constancy, all the other bacteria should probably be regarded more or less as accidental. And not alone that, but, notwithstanding the number of varieties which may be found at one level or another of the canal, the relative numbers of micro-organisms at different situations retain, during periods or intervals of digestion, a more or less definite proportion. Thus, the observations of Gilbert made upon the intestinal contents of dogs three hours after taking a meal of bread and meat showed an abundance of organisms in the stomach, a pronounced diminution in number in the duodenum, followed by a gradual augmentation to the ileocecal valve, where bacteria flourish in the greatest luxuriance. When the large intestine is reached there is a marked diminution in the numbers, with a slight increase proportionate to the distance from the cecum.

The importance of the stomach secretions in destroying bacteria has evidently been overestimated. The comparative frequency with which varieties of cocci were found in duodenal cultures by Cushing and Livingood tends to confirm this view; and the relative diminution in duodenum observers like Gilbert, Dominici and Escherich believe to be due to the dilution of the chyme by the biliary and pancreatic fluids, rather than to any very marked action on the part of the gastric juice. However this may be, experiments tend to show that there is a tendency on the part of the stomach to completely free itself, together with the end-products of digestion, from even micro-organisms which are resistant to the gastric juice. The normal viscus, then, when empty, is amicrobic; the same is also partly true of the duodenum.

The evidence of all recent studies sufficiently demonstrates that the only way to decrease the number of the intestinal flora is to decrease the number introduced with the food. Thus, on a purely milk diet Gilbert and Dominici found that a striking reduction in the number occurs. The observations of Cushing and Livingood fully attest the accuracy of these results. They further found that with an empty duodenum, during a period of fasting, practically no persisting bacterial elements could be demonstrated. During periods of active digestion, on the other hand, micro-organisms are often present in considerable numbers. Apparently, therefore, a close although temporary relationship exists between the flora of the ingesta and that of the entire digestive tract. The fact that bacteria do not lurk in or upon the mucous surface of the empty canal is one of most eminently practical importance, as will shortly be noticed.

That part of the work of Cushing and Livingood relating to surgical cases, illustrating the foregoing principles and their adaption to intestinal surgery, is of great interest; and will do much to encourage the application of these bacteriological results by other surgeons. Series of surgical cases were placed under varying conditions of diet preliminary to operation and the results of cultures from the bowel afterward noted. They were able to ascertain that when subjected to the ordinary methods of dietary preparation for anesthesia the number was generally reduced, but that in a certain group of cases, at all events, the preparation may not affect the organisms present in the canal and that these may be the cause of the ensuing peritonitis. Most important of all, they showed that by precautionary feeding, it is possible to bring about an amicrobic condition of the bowel with apparent certainty. This applies to a large class of cases, representing states of chronic gastritis from ulcer, carcinoma, dilatations, etc., with a percentage of hydrochloric acid varying from complete absence to a condition of hyperacidity. This amicrobic state is obtained by simple sterilization of all ingesta. The sterilization of the food cannot too strongly be insisted upon under these conditions. Pathologic bacteria are commonly enough found in food; for instance, it is astonishing with what great frequency streptococci may be found in such a universal food product as milk. Eastes (*Brit. Med. Jour.*, Nov. 11, 1899) in 186 specimens obtained from various sources found these organisms in 75.2 per cent. The mouth is rinsed with an antiseptic solution and the teeth are carefully brushed at intervals of a few hours, particular care being exercised before and after eating. When micro-organisms in numbers are found in the stomach-contents after a tested meal the stomach should be washed out morning and evening. Food is best given in small amounts and often from clean or preferably sterile vessels. Boiled water, sterilized milk, beef tea, albumen-water, and similar liquids may be given by the mouth, rectal feeding being substituted if necessary.

The simplicity of the method will appeal to all; its efficacy has been so thoroughly proven in such a large and varied group of cases that the striking results in patients operated upon for intestinal troubles invite prompt trial by all engaged in this kind of surgery. Peritoneal infection as a result of operations upon the stomach and intestines is too perilous a risk not to invite every effort to minimize its occurrence and dangers.

THE PREVENTION OF INSANITY.

Public opinion is only just ready for a discussion of this subject. Very wisely the attention of legislatures has first been called to the more imperative and economic side of the question, the "care" of the insane. The housing and clothing and feeding of the idiot and dement, as well as the confinement of the maniac, have been assumed by the tax-payer; and opportunity has been given to the relatives of these unfortunates to live their lives unhampered by the care of an insane person. This has insured greater care and a longer and more comfortable life to the patient than was generally possible under private care.

A further step has been toward the treatment of acute and curable insanities, and to this end much valuable pathological study of the morbid conditions of the brain has been pursued under State aid. The sociological relations of mental diseases to the community in the matter of ancestry, environment, occupation, and temperament, have been investigated, and alienists now stand in a position to state very definitely some of the most potent causes of insanity and to suggest how the increase of insanity may be prevented.

The increase of insanity must be admitted as a fact. After eliminating the elements which might give a false increase, such as the diminished death-rate owing to better care of the insane, the accumulation of senile cases, the better

means for obtaining statistics, the figures nevertheless show that there has been year by year a distinct *pro rata* increase, which, with a rapidly increasing population, makes a decided increase in the actual number of insane and a constant demand on the tax-payer for their care.

In England and Wales this increase, as reported by the Commissioners in Lunacy, was 3114 on January 1, 1899, over the preceding year. This fact, so startling from a social and economic standpoint, has furnished the text for a very practical and able discussion of the subject in an address on the "Prevention of Insanity" by R. Percy Smith, M.D., F.R.C.P. (Lond.), delivered at the opening of the Section of Psychology at the last annual meeting of the British Medical Association. He holds that the time has come when public opinion must be aroused to reduce the three great causes of insanity, *viz.*, (1) the propagation of the race by those of insane inheritance or those who have suffered from insanity; (2) the influence of alcohol; and (3) the causation of general paralysis by syphilis.

The first cause, "hereditary influence," gives the largest percentage of any cause of insanity and the most difficult to diminish by legal enactment. That there is a popular knowledge of the danger of marrying with insane inheritance is seen in the gossip connected with such marriage and often the wilful suppression of a taint in the family history where the marriage of sons or daughters or property are concerned; and it is well understood that cousins, when there is insanity or serious neurosis in a common ancestor, should not marry; but public opinion should be cultivated to understand the danger arising from the marriage of any two neurotic individuals, and that no person of insane or neurotic inheritance should marry another of insane or neurotic inheritance, even although their own health be apparently sound. It is the duty of the medical profession to advise against such marriages, and to point out the almost inevitable fatal result in the offspring.

With reference to the marriage of persons who have suffered from an attack of insanity, a prohibitive legislature would doubtless do much for the community. Such an enactment is in force for congenital imbeciles and chronic epileptics in some communities and should be made universal; but as the danger in such cases is more glaring and asylum restriction careful, there are not as many unsound offspring from such individuals as from the marriage of persons who have been temporarily insane. Medical opinion should forbid absolutely the marriage of any one who has suffered from an attack of insanity, and should advise against childbearing in women who have had attacks of puerperal mania due to inherited neurosis.

Next to direct inheritance, alcohol counts for the most potent influence in the causes of insanity. The alcoholic insane form about one-quarter of all admissions to asylums in England. They are generally the most dangerous and difficult to manage and in private life do the most harm. Many who are not included in the statistics of the insane are temporarily unsound and are free to abuse their families, ruin their health, and produce offspring of such neurotic tendencies that they are almost sure to join the ranks of the alcoholic insane in the next generation.

This is a matter in which careful legislation might aid the cause of society. Drunkenness, habitual or intermittent, when it interferes with the laws of society, should be subject to compulsory detention and treatment as much as insanity. "Even those," says Dr. Smith, "who hold the liberty of the subject so sacred as to wish to leave the alcoholic to drink himself to organic disease or insanity and his family to poverty might at least turn their attention to the fact that nearly a quarter of the insane are so either wholly or in part from a wholly preventable cause, and that in a large proportion of these cases the tax-payer has to bear the expense."

There seems to be no logical reason why legislature should not take as severe steps to prevent the spread of so ravaging a disease as syphilis as it does of measles or smallpox. If there were no syphilis, it is pretty safe to say there would be very little general paralysis, and another large and preventable cause of insanity would be eliminated. It is the opinion of Dr. Smith that if syphilis were made a notifiable disease, and the chances of its spread diminished, we should see a corresponding diminution in the number of cases of general paralysis, which ought to be looked upon as a truly preventable disease. As a proof of this statement it might be noted that in Finland, as the result of the hospital treatment of syphilis and the power given by the legislature enabling the compulsory examination of any suspected individual, syphilis has much diminished in the course of twenty years.

In our large cities where syphilis, alcohol, and fast living are most rife and where, in consequence, general paralysis occurs most frequently, it would be difficult at present to legislate these causes of insanity out of existence; but it would

be a long step toward improvement to get the public to realize that insanity is not an "affliction of the Almighty" or a "mysterious dispensation of Providence," but a disease which in most cases individuals bring upon themselves, or with their eyes open, hand down to their children.

If our race is to hold its own in the struggle for existence with other nations, it must not be reproduced by the individuals of weak nervous systems and degenerate or alcoholic types that are at present filling our asylums. The legal and forcible detention of all such by the State, with prohibitory marriage laws, will doubtless help the next generation; but medical advice and teaching to arouse public sentiment must do the rest.

THE MALARIAL EXPERIMENTS.

Newspapers of a certain class exploit so many discoveries in science, with so little regard for accuracy, that we are tempted to believe that they do it for the sake of making double copy in overthrowing the rumors that they have started.

But for once some of the English and Continental journals have overreached themselves and have begun to report exaggerations where none existed, and to deny the truth of conclusions that were perfectly just concerning the experiments to test the mosquito theory of malaria in the Roman Campagna.

As is well known, Dr. Luigi Sambon and Dr. G. C. Low, both connected with the London School of Tropical Medicine, have been living since June, 1900, in the malarial valley near Ostia, where the pestilence is so great that travelers who merely spend a night there generally contract the disease. They have lived in a mosquito-proof hut, and have not taken any quinine or other drugs preventive of malaria, with the result that neither they nor their attendants have had any symptoms of the disease. Nevertheless a report that the experiment had proved a failure was being widely spread to the public, until the *British Medical Journal* promptly settled matters by telegraphing for direct information. The following reply was received by the London School of Tropical Medicine:

Rome, 13 Sept., 6.25 A. M.

To Manson, Finically, London.

Assembled in British mosquito-proof hut having versified (verified) perfect health experimenters amongst malarial-stricken inhabitants, I salute Manson who first formulated mosquito theory. Grassi.

The experiment at this date had still six weeks to run before the malarial season—and the mosquitoes—would disappear, but the demonstration of the formula "No mosquito, no malaria," seems to be satisfactory.

In further proof of it, Dr. Elliott, a member of the Liverpool expedition sent to Nigeria some time ago to investigate the subject of malarial fever, reported on his return that the members of the expedition had spent four months in some of the most malarious places, marshes and lowlands that were considered the most deadly. They had taken no quinine, but had carefully used mosquito nets at night, and not one of them had contracted the fever.

The positive side of the experiments on the mosquito theory of malaria is no less authentic and interesting. Dr. Manson's son, who had not been in a malarial district for many years, offered himself for experiment, as a complement to his father's work. He allowed himself to be bitten by mosquitoes that had been carefully brought from Rome, where they had been fed on the blood of a malarial patient. He contracted malaria of the double tertian type and the organisms were found by microscopical examination in his blood. The whole experiment was conducted and verified by scientific men; so that there remains no doubt but that the mosquitoes carried the organism from Rome to London. A similar experiment made in Bellevue Hospital, New York, gave like results. A young man permitted himself to be bitten by mosquitoes that had been fed on the blood of a malarial patient, and six days later began to show signs of malarial infection. While these observations of Berkely have not been carried to their final stages, the evidence already adduced by him tends in large part to substantiate the observations of Manson and of Ross. Anopheles claviger is not an uncommon form of mosquito with us and our experimenters have ample opportunities for investigating the truth of Manson's claims.

This discovery, while not wholly solving the malaria problem, is nevertheless undoubtedly true, as far as it goes. Mosquitoes are one of the main causes of malarial infection. The benefit to mankind of the work that has been done by scientific men who have been laboriously working out these experiments for the last few years is too great to be estimated, and it is grievous to have the much-believing public ready to accept their conclusions with an incredulous smile born of many previous deceptions.

ECHOES AND NEWS.

NEW YORK.

Dr. Doremus' Golden Wedding.—Dr. and Mrs. R. Ogden Doremus celebrated their golden wedding October 1, 1900.

New York Neurological Society.—At the last regular meeting of this Society, held October 2d, Dr. A. R. Defendorf read a paper on "Periodical Psychoses;" Drs. L. P. Clark and T. P. Prout on "Status Epilepticus: Its Nature and Pathology."

Gouverneur's New House Surgeon.—Dr. Frank P. Leadley, for the past two years house surgeon of Gouverneur Hospital, last week formally turned over the institution to his successor, Dr. Agnew H. Hilsman. The former will take up the practice of his profession in Rochester, N. Y.

Academy Notes.—Medicine once more takes on its wonted activity in this city after the summer's holiday. The Academy had its first general meeting, Thursday, October 4th, at which Dr. Jacobi read his complete report on "Infant Feeding," which was presented in abstract at the Thirteenth Medical Congress. Monday, October 8th, the Section on Surgery meets. Papers by Drs. J. F. Erdmann and A. B. Johnson will be read. New instruments will be shown by Drs. Willy Meyer and Carter Cole. On Thursday, October 11th, the Section on Pediatrics presents a discussion on the subject of "Antitoxin in Diphtheria." Papers will be read by Drs. H. F. Koester, W. H. Park and J. H. McCollom. Discussion by Drs. J. W. Brannan, W. P. Northrup, W. C. Deming, L. K. Neef and C. S. Benedict.

Insanity at Elmira.—An alarming increase of insanity among the convicts at the Elmira Reformatory has been reported to State Superintendent of Prisons Collins since March last, which period marked the close of the Brockway administration. Since March sixty-five insane convicts have been transferred from that institution to the State Hospital at Matteawan. The State prison authorities cannot account for the increase. The interpretation of this report is probably as follows: Many of the patients there were suffering from some form of mild psychosis, moral dements, paranoiacs, etc. Coming under a physician's eye their mental irresponsibility has been recognized and hence they have been transferred to the proper institutions.

Bellevue's Undesirable Help.—Inspector Robert W. Hill has published his report on visitations to the public hospitals and almshouses within the First Judicial District, which comprises the boroughs of Manhattan and the Bronx. The most interesting feature of the report, which is submitted to the State Board of Charities, is its sharp criticism of the present "poor help" system which is in use in the Bellevue Hospital and several other charitable institutions. Much of the coarser kind of work is done, not by regularly paid employees, but by men and women who are without a home and who are glad to obtain shelter and food in return for their services. The inspector found fifty-one women of that class located in an attic in one of the pavilions of Bellevue Hospital. On a stand in an antechamber he found seven empty whisky bottles, which had been smuggled in by the women the night before. Speaking of this kind of help, the inspector says: "These persons would be better off if sent over to the almshouse and the work which they are supposed to do given to paid employees. If better quarters were provided for the help, it would be possible to secure a better class, but so long as their present dormitory system continues the class of help will continue undesirable."

Dr. Lewis A. Sayre.—At a special meeting of the Executive Committee of the New York County Medical Association, held September 24, 1900, the following resolutions were unanimously adopted:

Whereas, It is our sad duty to announce the death on September 21, 1900, of our late associate, Dr. Lewis Albert Sayre, one of the founders of the American Medical Association, and its President in 1880; therefore be it

Resolved, That we place on record our high appreciation of the valuable services which he has rendered to medicine and surgery during his long and useful life;

Resolved, That his daring originality, his freedom from surgical traditions, along with his unflagging enthusiasm and interest in everything pertaining to his beloved profession, constituted him a teacher of rare excellence, whose pupils will cherish his memory long after the voice of their preceptor is hushed;

Resolved, That we extend, in the name of the members of the New York County Medical Association, our heartfelt sympathy to the afflicted relatives, and direct that a copy of these resolutions be sent to the family and to the medical journals.

Obituary.—Dr. Samuel Smith Purple, one of the early presidents of the New York Academy of Medicine and founder of the library of that institution, died at midnight Saturday at his residence, 36 West Twenty-second Street, from heart trouble, after a short illness. Dr. Purple was born in Lebanon, Madison County, N. Y., June 24, 1822, and was graduated at the medical department of the University of the City of New York in 1844. In 1846-48 he was physician at the New York City Dispensary, and was ward physician under the Board of Health during the cholera epidemic of 1849. He was vice-president of the New York Academy of Medicine from 1870 to 1875 and its president from 1876 to 1880, and was made second vice-president of the New York Genealogical and Biographical Society in

1888. He is the author of a large number of medical works. Dr. Purple's presentation of 4000 volumes to the New York Academy of Medicine was the beginning of that institution's library. At the time of his death he owned one of the largest private libraries in New York. Dr. Purple was unmarried.

Brooklyn Crowded.—The new census is showing many interesting facts relative to congestion of population. Taking the figures of the tenement-house population in Brooklyn, supplied recently by Dr. Byrne of the Health Board, and which had to do with 574,950 persons, or 49.2 per cent. of 1,166,582, Brooklyn's population, it is found that there is an average of 18.1 persons to a dwelling. To-day half of Brooklyn is housed as densely as Manhattan's population was in 1890. In that year Manhattan's entire population was housed at an average of 18.52 persons to a dwelling. It is seen that while Manhattan is yet the leading area of the world in the intensity of its housing problems Brooklyn is at least second in America. Figures obtained from the Department of Buildings in the boroughs of Manhattan and the Bronx show that the number of persons to a dwelling in Manhattan at the present time is 23.2.

PHILADELPHIA.

Scored by Coroner.—At an inquest over the body of a suicide recently the Coroner severely scored a morbidly curious man. The latter had gained access to the house by representing himself as a deputy from the Coroner's Court.

Water Company Arraigned.—The Springbrook Water Company of Wilkes-Barre has been charged with violating a city ordinance by furnishing impure water. Forty citizens, including councilmen and physicians, testified against the Company. The penalty is $100 for each day.

Epidemic of Diphtheria.—Diphtheria is epidemic in Millville, a suburb of Altoona. The State Board of Health was appealed to, but refused aid because of lack of funds.

Philadelphia Almshouse.— The Board of Charities and Correction has decided to add four graduates in dentistry to the staff of residents at the Almshouse. One is to be chosen from each of the four schools of dentistry here. They are to receive no salary.

New Society of Nurses.—The Philadelphia Society of Graduate Nurses has been organized and chartered under State laws with Joseph Haines as president. The object of the Society is to elevate the standard of nursing and to furnish the public with first-class nurses.

Whipping Post for Wife-Beaters.—The September Grand Jury has recommended the reestablishment of corporal punishment for wife-beaters. The members are also of the opinion that houses of refuge and reformatories for incorrigible boys do not tend to make good citizens, and recommend discharge with a caution for the first offence and punishment in the shape of a sound thrashing for succeeding offences.

Druggists Aroused.—The druggists of this city are aroused over what they call an unwarranted investigation of their affairs by the State Pharmaceutical Examining Board. A special agent of the Board is endeavoring to ascertain the competency of drug-clerks and also the cautions observed in the sale of poisons It is believed that an effort is to be made to have the Legislature pass more stringent laws governing the sale of drugs.

Public School Hygiene.—School-teachers and janitors are wondering how they will enforce all the rules lately promulgated by the Board of Education, among others are the following: Teachers should forbid spitting on the floors. Children should be discouraged from eating candy at recess. Children should be required to put on overgarments during recess in cold weather, and urged to go into the open air. When a child appears with a soiled skin a note should be sent to the parents calling attention to that fact. The sanitary care of the houses is strictly enjoined.

Changes in Medical Schools.—The various medical schools of the city opened October 1st. The new year at the Medico-Chirurgical is marked by the completion of the new laboratory and dispensary building. The faculty of Jefferson has recommended that a laboratory of clinical medicine be established in connection with the proposed new hospital, the laboratory to be known as the J. M. Da Costa Memorial.—Dr. H. F. Harris has resigned the associate professorship of pathology.—At the University of Pennsylvania the first-year classes in medicine and dentistry are smaller than usual because of increased entrance requirements. Provost Harrison stated that the teaching of medicine was to be based upon scientific considerations instead of being viewed from a commercial standpoint. A radical departure in the medical curriculum is the confining of anatomy to the first year and physiology to the second year only, instead of extending both over the two years.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Senor Alvarenga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1901, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the Secretary of the College on or before May 1, 1901. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within

the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award.

The Alvarenga Prize for 1900 has been awarded to Dr. David De Beck, of Cincinnati, Ohio, for his essay entitled, "Malarial Diseases of the Eye." Thomas R. Neilson, M.D., Secretary.

CHICAGO.

Norwegian Hospital.—The medical staff of this institution has founded a library for the use of patients and attendants. It consists of 500 volumes and represents an outlay of about $1000.

South Chicago Hospital.—This will soon be opened. A house containing thirteen rooms has been purchased and is now being renovated and prepared for patients.

Appointment of Dr. Pennington.—Dr. J. Rawson Pennington has accepted the Chair of Rectal Surgery in the Chicago Policlinic. Formerly he held a similar position in the Chicago Clinical School. He will assume his duties at once.

Appointment of Dr. Parker.—Dr. William R. Parker has been appointed Commissioner of Health of Evanston, to succeed the late Dr. A. B. Clayton. The appointment was confirmed by the City Council.

Illinois Medical College.—At the Sixth Annual Commencement of this College, recently held, nineteen men and one woman received the degree of Doctor of Medicine. The degrees were conferred by President Randolph N. Hall, after which the Doctorate Address was delivered by Professor Robert H. Walsh.

Metropolitan Medical College.—On the petition of Attorney-General Akin, Judge Haney has issued an injunction restraining the officers of this institution from conducting its business in violation of the terms of the charter. At the final hearing of the suit the Court is asked to dissolve the corporation, which is declared to have conducted a fraudulent business and abused and violated its charter since its organization in September, 1896. The basis of the petition is that the college, while advertising that it is a legitimate institution, does not require personal attendance of applicants for the degree of Doctor of Medicine. The specification states that "this system of conferring degrees is dangerous to the health of the people, is a usurpation, misuse and abuse of the power conferred upon said college as a corporation."

Injurious Desks.—Acting under the directions of Dr. W. S. Christopher of the Board of Education, the child-study department has taken up the question of desks and the effect of the present accommodations on the health of the pupils is being carefully investigated. The Committee will probably present a report in a few weeks. If it is not favorable to the desks now in use, a strong effort will be made to change them.

Dentists Poisoned at a Dinner.—Twelve of twenty-four members of the Delta Sigma Delta fraternity were poisoned by food eaten at a dinner September 29th. Canned salmon is thought to be the cause of the ptomain-poisoning. Although some of the men are still in a serious condition, it is not thought any of the cases will prove fatal. All afflicted are dentists. Commissioner Reynolds of the Board of Health has secured samples of the food eaten for chemical analysis. The salmon was obtained out of town, and it believed to be a lot from a burned cold-storage plant at St. Paul that was suspected. The Health Department has been trying to keep it out of Chicago.

GENERAL.

Huxley Lecture.—Lord Lister delivered the Huxley Lecture for 1900 at St. Martin's Town Hall on October 2d.

University of Glasgow.—The Chair of Clinical Medicine at the University, made vacant by the promotion of Dr. McCall Anderson, an appointment for life with fees and salary aggregating $1170, is being eagerly sought for by the following candidates: Drs. James Finlayson, Samson Gemmell, G. S. Middleton, J. L. Steven of Glasgow and by D. A. Morison of London.

European University News.—Dr. Constantin Savas has been appointed ordinary Professor of Hygiene and Bacteriology of the Athens medical faculty.—Breslau University has elevated Dr. Richard Stern from private-docent to extraordinary Professor of Internal Medicine.—At the University of Copenhagen Dr. Oscar Wanscher has been promoted to extraordinary Professor of Surgery.—Dr. Oscar Schulz has been appointed private-docent in Physiological Chemistry at the University of Erlangen.

Cuyahoga Ohio County Medical Society.—At the October meeting of this Society a symposium on appendicitis will be held. The following papers are to be read: "Etiology of Appendicitis," Dr. Guy H. Fitzgerald; "Diagnosis of Appendicitis," Dr. Charles B. Parker; "Diagnosis of Appendicitis," Dr. Charles G. Foote: "Medical Treatment of Appendicitis," Dr. L. B. Tuckerman; "When Shall We Operate," Dr. Frank E. Bunts; "Operation in the Interval," Dr. N. Stone Scott; "Operation During Attack," Dr. Geo. W. Crile; "Complications During Appendicitis," Dr. Morris Stepp; "Appendicitis and Typhoid Fever," Dr. Charles J. Aldrich; "Appendicitis in Children," Dr. Joseph V. Kofron; "Appendicitis and Pelvic Disease," Dr. R. E. Skeel: "When Do I Call the Surgeon?" Dr. J. H. Lowman; "Hernia Following Operation for Appendicitis: Causes and Means of Prevention," Dr. Carl A. Hamann.

Woman's Medical Fraternity.—The Syracuse Society retracts its claim to be the first woman's medical fraternity.

Asphyxiation in an Asylum.—Ten inmates of the insane ward of the Lowell (Mass.) city farm narrowly escaped asphyxiation by gas at an early hour September 29th.

Morphine Habit in a Dog.—An Irish setter owned by a physician of Philadelphia was recently run over and had his back severely injured. Feeling sure the dog would die, the doctor began to experiment with morphine. One morning he forgot to give the dog its injection. It crept into the office and lay at the doctor's feet. He was unable to understand its queer antics. Finally it crawled to the medicine chest from which he had taken the morphine, and, looking up at the chest, it began to whine. The doctor wondered if the dog was really trying to make him understand that it wanted its injection. He took the hypodermic from the chest. When the dog saw the syringe, the report says that it barked gladly and lay on its back, whining for the doctor to inject the drug.

Beer for Hiccoughs.—Hiccoughs bid fair to become as popular a malady in prohibition districts in Kansas as snake-bites have been in the past. After hiccoughing without intermission for 100 hours Dr. H. A. Pickerel of Beverly was brought to Salina, and twenty-two hours later he was cured of his trouble by a bottle of beer.

Medical Society of Missouri Valley.—This Society held its annual meeting at Council Bluffs, Iowa, September 20th. Three sessions were required to complete a most interesting program, and later, at the Grand Hotel, the members gathered around the festal board, where they recuperated from the labors of the day. The Society voted to contribute $25 to the Rush Monument Fund, and a resolution was adopted providing for a banquet after each meeting. The following officers were elected: President, Dr. V. L. Treynor, Council Bluffs; First Vice-President, Dr. B. B. Davis, Omaha; Second Vice-President, Dr. F. E. Sampson, Creston; Treasurer, Dr. T. B. Lacey, Council Bluffs; Secretary, Dr. Chas. Wood Fassett, St. Joseph. The next meeting will be held March, 1901, in Omaha.

Cider as a Cure of Gout.—The largely increased consumption of cider far away from the producing counties, to which it was almost confined a few years back, shows, at all events, that a good many people prefer a less heavy drink than beer. But the enthusiastic advocates of the West Country beverage begin to advance far more ambitious pretensions on its behalf. Not only do they proclaim it an antidote to gout, and relate how a certain Royal Duke once cured himself of that disorder by restricting himself to pure Devonshire cider, but the pleasant tipple is represented as having remedial effects in many other diseases.

Poison Ivy.—Dr. Pfaff of Harvard has investigated the poison of *Rhus radicans* and finds it to be a non-volatile oil, present in every part of the plant, which cannot be washed off the skin with water alone. It is said that a remedy has been discovered in the form of a saturated solution of alcohol, of 50 to 75 per cent. strength, and sugar of lead; and that its efficacy has been tested by the Department of Agriculture.

Yellow Fever.—A board of officers, consisting of Major Valery Havard, Surgeon, and Major William C. Gorgas, Surgeon, United States Army; Surgeon A. H. Glennan, United States Marine-Hospital Service; Dr. Augustin Varona, Dr. Vincente Benito Valdes, and Acting Assistant Surgeon T. C. Lyster, has been meeting at Havana, Cuba, for the purpose of inquiring into and reporting upon the feasibility and advisability of establishing a detention camp near Triscornia, Cuba, for the detention of immigrants who arrive at Havana, in order that the spread of infection may be prevented.

Pan-American Medical Congress.—The third meeting of the Pan-American Medical Congress, as already announced in the Medical News, will be held in Havana, Cuba, December 26, 27, 28 and 29, 1900. Invitations from the Secretary of the Executive Committee have been received and members are urged to specify their intention of going to the Congress and further asked to forward the titles of papers to be read to Dr. T. V. Coronado, Prado 105, Havana, Cuba, Secretary of the Committee on Organization.

The Cause of Temperance.—A British temperance journal has been publishing a prescription for "a substitute for brandy" in cases of faintness or severe pains. It consists of "equal parts of the strongest tincture of ginger, sol volatile and chloric ether." Temperance people have had the recipe printed on cards and distributed with the injunction: "Pass it on." The *Lancet* points out that brandy usually contains about 50 per cent. of alcohol, whereas of the temperance ingredients the tincture of ginger is essentially pure alcohol, the sol volatile contains alcohol in the proportion of 6 parts out of 9½ and the chloric ether has 95 per cent. of alcohol. The mixture, therefore, contains 83 per cent. of alcohol compared to 50 per cent. in brandy, and is, no doubt, extremely efficacious.

Cost of Medical Education in London.—According to the *Lancet* the minimum sum a student must be prepared to spend in London during a year on board and lodging is $300. He can, however, save 20 per cent. of this expenditure by living with a fellow-student. He must be prepared to spend at least $50 more in books and instruments. He will be almost the exception if he does not incur one or two extra liabilities in the way of special tuition during his five years' career. He will require another $50 for pocket money, and to these figures must be added his

fees and the price of his clothes. "We do not think that in London any young man should be asked to attempt to maintain himself and pay the necessary fees and expenses of his medical education upon a less sum than $500 a year. If a student cannot command personally, or by allowance from his parents, $500 per annum, and look to receiving it regularly for at least four out of the five years of his curriculum, we consider that he is rash, in these exacting days, to embark upon our profession."

The "Salt-Lake."—At Odessa the so-called Limancure is becoming popular. The Limans are sheets of water originally connected with the sea, but which have been isolated and converted into salt lakes. Owing to evaporation their waters have become concentrated, and are thought to possess considerable therapeutic value. There are three of these Limans near Odessa. The principal salts they contain are the chlorides of sodium, potassium, and magnesium; calcium sulphate and magnesium, or sodium bromide. Their bottoms are covered by a black slimy substance composed of a sponge of animal and vegetable matter impregnated with salt water, and contains iodine, bromine, sulphur, sulphuretted hydrogen, and oleic and valerianic acids. Patients bathe either in the open lakes or in baths with the water at various temperatures and degrees of concentration. They also have slime baths. The diseases treated are chronic rheumatic affections, scrofula, rickets, stiffness of the limbs, and certain chronic skin diseases. Considerable discomfort (depression of spirits, digestive disturbances, palpitations, etc.) is frequently experienced at the beginning of the cure, but soon passes off.

The Plague in Egypt.—The Sanitary Department of the Ministry of the Interior at Cairo has just issued a report on the plague in Egypt, covering the period from May, 1899, to July, 1900. It begins with a full account of the outbreak in Alexandria, which began in the first-named month and the last case of which occurred on the 5th of the November following. In all 96 cases became known to the authorities, and it was estimated that 27 more, of mild character and followed by recovery, might possibly have escaped notification. These 96 were made up of 66 natives and 30 foreigners, the latter mostly Greeks, Frenchmen, or Italians employed in groceries, bakeries, wine shops, or at restaurants. The mortality among reported cases was 48 per cent., and there was reason to believe that no death from plague escaped notice. The precautions taken for arresting the course of the disease appear to have been admirably devised and conducted, and are set forth under the three heads of: (1) Measures to assure prompt discovery of each case of plague, and of all suspicious cases; (2) direct measures to prevent the propagation of the disease from individual cases; and (3) indirect measures, such as general cleansing of dirty quarters, with a view to eliminate all conditions favorable to the existence or propagation of the disease. A sum of £30,000 (Egyptian) was granted by the Caisse de la Dette to defray the extra expenses, and was placed at the disposal of the Director-General of the Sanitary Department, but the total outlay exceeds this sum by £4000 (Egyptian), and the whole of the work required is declared to have been carried out with great discretion and tact, and with the minimum of offense to religious or other susceptibilities of the natives.

Cancer in Germany.—The Prussian Government has initiated systematic inquiries with a view to amplifying the world's knowledge on the subject of cancer. Every registered physician has received a paper of questions calling upon him to give his experiences in cancer cases. The principal points are whether cancer is hereditary and contagious, whether it is connected with a particular habit, such as indulgence in alcohol, tobacco, etc., or whether it is more prevalent in one district than another.

The Plague at Glasgow.—New developments concerning the plague situation at Glasgow indicate the gradual abatement of the epidemic. About five new cases have been reported during the past week. All of these occurred in suspects and were immediately isolated.

CORRESPONDENCE.

INFECTION AND INTOXICATION.

To the Editor of the Medical News:

Dear Sir: I have read with profit the interesting and suggestive communication by Dr. Eugene Wasdin on "Toxicity versus Septicity in the Infectious Pathogenic Bacteria," and wish merely to make a plea for the abandonment or, at least, the more qualified use of the terms "sepsis," "septicemia," "sapremia," and their derivatives, as being vague and indefinite, if not actually ambiguous. These words came into use at a time when our conceptions with regard to infection and intoxication were much more crude and less sharply defined than they are at present, and they were indiscriminately applied to both of the states mentioned, but now, when it has become so important to appreciate their differentiation, the necessity for precision in expression must be obvious. "Infection" may be defined as "a condition dependent upon the lodgment and activity of parasites in or upon the body." It may be local or general, and in the latter event, when the parasites are bacterial, the designation "bacteremia" may be employed. "Intoxication" or "toxemia" may be due to the products of bacterial activity, to the retention in the body of products of abnormal metabolism, qualitatively or quantitatively, or to the introduction of poisons from without.

Augustus A. Eshner.

Philadelphia, October 1, 1900.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, September 22, 1900.

THE PLAGUE IN GLASGOW—SANITARY PRECAUTIONS—THE OUTBREAK SUBSIDING—PRECAUTIONS IN LONDON—DEATH OF SIR J. B. LAWES—THE HOSPITAL COMMISSION IN SOUTH AFRICA—MR. TREVES ON THE HORRORS OF WAR—DEATH FROM A BEE-STING.

Although a large amount of attention has been devoted to the outbreak of plague in Glasgow, its source has not been definitely ascertained. All that is known is that the man in whose house the first case occurred worked as a dock laborer exclusively in vessels trading with home ports. He became ill after his wife and grandchild had died, presumably from plague, and may have been infected from them. They were supposed to be suffering from "acute gastroenteritis" and "zymotic enteritis" respectively. The man became ill on the day following his wife's funeral, which took place on August 11th. In a house in a neighboring street the disease suddenly developed in a family which had visited the first during the illness. A child aged ten years was taken ill on August 19th and died on the 21st. The doctor who was called in ten minutes before death diagnosed "acute pneumonia." On the 20th the mother, on the 22d a brother, and on the 23d a half-brother, aged three became ill. The two doctors who attended the patients were puzzled as to the nature of the disease. They regarded it as certainly infectious and notified it to the health authorities as possibly typhoid fever. In the cases of the dock laborer and the subsequent ones the disease proved to be plague, the bacillus being found in all. The patients were removed to hospital. In another neighboring street a woman who had recently been confined was taken ill on August 25th with symptoms resembling those of typhus fever, but the case proved to be one of plague. She had associated with the first family during their illness. A search was made in the houses in which the disease occurred and two other cases were discovered. All the persons who had visited these houses (80) were removed to reception-houses of the sanitary department. Four subsequently developed plague. Two other cases were found in houses near those in which the disease had occurred in men who appear to have been in contact with the patients. Most elaborate precautions have been taken by the authorities to check the spread of the disease. The district in which the outbreak occurred has been placed under special sanitary rules. Ashpits will be emptied three times a week and washed once weekly with chloride of lime whitewash. Dirty back courts will be hosed every night with chloride of lime solution. A special inspection of the district has been organized for the detection of dirty and overcrowded houses. The occupants of infected houses and all those who have been in contact with patients will be offered inoculation with Yersin's serum; those living in the neighborhood, with Haffkine's prophylactic. The nurses in charge of the cases have already been inoculated. Ratcatchers have been employed to clear the district of rats. A rather alarming fact is that a fatal case has occurred in the adjoining burgh of Govan on the south of the Clyde immediately below Glasgow. Clinically, the disease has manifested itself in three forms, (1) cases with solitary bubo; (2) cases in which several groups of glands were involved, and (3) mild cases which could not be recognized but for the history of infection. Should any cases of plague occur in London the Local Government Board is well prepared to combat the disease. At the British Institute of Preventive Medicine there is a store of Haffkine vaccine for inoculating suspected persons and arrangements for isolation have been already made. Every vessel arriving at the port of which the slightest suspicion is entertained is boarded and inspected by the sanitary authorities. The official bulletin issued at Glasgow shows that the position is as follows: In hospital suffering from plague 13, suspected 1, in reception-houses under observation 111. As the maximum period of incubation is fourteen days, it is now hoped that the outbreak has spent itself. The last report raises the cases in hospitals to 16 and the persons under observation to 112.

The death is announced of Sir J. B. Lawes, the great agriculturist, who a lay paper declares has done more good for his country than the whole race of politicians. To him more than to any other man was due the wonderful change that has taken place in agriculture during the past sixty years. He introduced the process for converting bones into soluble phosphatic manure. In conjunction with the celebrated chemist, Dr. Gilbert, he carried out a number of important feeding experiments on live stock which have been extensively quoted in physiological works. They invented a number of different manures to be used according to the nature of the crop to be raised, corn, barley, oats, or grass. The ingredients consisted of varying quantities of potassium, sodium and magnesium sulphates, superphosphates and ammonia salts. The wonderful effect of these manures is shown by the fact that in one case where the wheat manure was used the average yield was 59 bushels of corn and 41⅛ cwt. of straw per acre, whereas the unmanured plots of the same land only gave 19⅞ bushels of grain and 10¾ cwt. of straw.

The Hospital Commission has held sittings at Bloemfontein. Major Bedford detailed the disposition of the various hospitals. He admitted a shortage of ten field hospitals and said it was most difficult to meet requirements as operations extended. When the Army landed everything was practically upset. In Natal, whenever a unit arrived, it was sent where it was required with the result that the bearer companies and field hospitals got very much mixed. Colonel

Exham, the principal medical officer, said that the largest number of men in hospital at one time was 5000 and the maximum number of patients sent down to the base in one fortnight was 2000. Bloemfontein never suffered from lack of medical officers or equipment. In one month the hospitals dealt with 13,000 sick, a number which would tax the resources of London. At Hex River the Commission unexpectedly met an ambulance train on the way from the front and paid it a surprise visit of inspection. Several patients were questioned and all said they were satisfied with their treatment.

Mr. Treves thus describes his first experience of the battlefield: "I do not know that I ever wish to see a battlefield again; the horrors of it cannot be exaggerated. People have expressed a hope of seeing the fun! Well, I found it very sorry humor indeed. The heat was very intense and poor "Tommy" came back to the camp almost unrecognizable by reason of blood, and dazed and speechless from thirst. Everybody longed for the night." Describing the hospital arrangements, he says: "We had no camp to go to, so the nurses slept on the boards of a looted store and I slept in a cart. Better nurses and more devoted women I never met; they gave poor "Tommy" all they had—their water-bottles, their handkerchiefs, and even their mattresses to lie on. Their very presence amongst the dead and dying was something, and they thought of means of relief that would not have occurred to us men."

A short time ago I sent an account of a case in which a bee-sting proved fatal to a young lady. Another case has just occurred in which the patient was a child ten months old. It was stung while lying in its cradle and death supervened in a few hours. At the necropsy it was found that the child had been stung over a vein on the face which gave rise to cerebral thrombosis.

TRANSACTIONS OF FOREIGN SOCIETIES.

British.

ASTHMA AND THE FRONTAL SINUS—APHASIA AND HEMIPLEGIA—PATENT DUCTUS ARTERIOSUS—FILARIA SANGUINIS AND MOSQUITOES—TRAUMATIC RUPTURE OF THE HEART—RESIDUAL URINE AND THE PROSTATE—OCULAR PARALYSIS—INFLUENZA AND PARALYSIS—SYPHILIS AND LUPUS—MYXEDEMA IN THE MALE.

L. Turner, at the Edinburgh Medico-Chirurgical Society on July 4, 1900, exhibited a man afflicted with asthma and chronic suppuration of the left frontal sinus and left maxillary antrum. The antrum was first opened, evacuated and drained. Later the frontal sinus was trephined, curetted and drained. Trickling of pus into the nose thereupon ceased and the asthma improved greatly.

W. Russell exhibited (1) the brain and heart from an aphasic and hemiplegic of long standing. Sunstroke had occurred twelve years previously. In the left hemisphere were many large cysts, fluid contents, due to embolism of one of the middle meningeal branches. The heart showed old vegetative endocarditis, especially mitral in side. An old aneurism of the aorta also was present. (2) The brain of a recent case of aphasia and hemiplegia. The lesions almost duplicated the above, but were due to thrombosis following extensive middle meningeal atheroma. The thrombosis and embolism had produced the same effects, namely, brain-tissue softening and cyst formation.

Dr. Pearson for G. A. Gibson showed (1) a patent ductus arteriosus, diagnosticated during life and proved by autopsy, due to right lobar pneumonia. (2) Specimens of filaria sanguinis lodged in the proboscis and muscle of a mosquito.

H. Littlejohn displayed (1) the heart of a youth caught between the buffers of two railway carriages. Although there was no external traumatism and no fractured rib, the right auricle was ruptured for nearly two and a half inches. (2) The stomach from two carbolic acid suicides; the first, ten ounces of the acid having been taken, presented the typical contracted, leathery appearance, with thick white putty-like material over the mucosa; the second took ordinary disinfecting carbolic solution out of a beer-bottle and died in fifteen to twenty minutes, although the solution was weak. The point learned from these specimens is that the stomach-tube should always be used although the poison may have been corrosive. The danger of puncture by the tube is much less than of absorption of the drug left in the organ. (3) The liver and other organs from a case of acute yellow atrophy of the liver or of phosphorus poisoning. The patient was illegitimately pregnant and marriage had been refused by her lover. Abortion followed ingestion of the poison and death in thirty-six hours. The uterus was normal and precluded the possibility of septicemia. The liver was atrophied. The tests for phosphorus had been negative but that did not preclude the likelihood of this drug having been used. The stomach was also shown to illustrate post-mortem digestion.

A. Bruce showed the brain of a long-standing aphasic and right hemiplegic. His symptoms had been good comprehension of spoken language, faulty comprehension of written language; unintelligible voluble utterance; good memory and utterance of music, in songs the words were lost, but the rhymes preserved; extraordinary power of mimicry. A zone of softening extending along almost the whole fissure of Sylvius, the superficial portions of the temporal lobe escaped, and the angular and marginal gyri were almost entirely free from softening.

A. G. Miller read a clinical note on residual urine and enlargement of the prostate. Catheterism early established appears to be the ordinary way of dealing with the enlarged prostate and residual urine. The condition of the gland in itself need not be especially disastrous,

but when the residual urine appears at all in large quantity the real trouble begins. In the normal individual the bladder distention reaches a certain point, causes discomfort and leads to emptying. This function is usually accomplished by voluntary relaxation, involuntary expression and atmospheric pressure. Thus, by habit when the prostate hypertrophies and offers a mechanical bar, really no voluntary expulsion is performed. He quoted a case in which under instructions the patient, instead of at once taking to catheter-life, first voided his urine, then after a few moments made a direct voluntary effort to really empty the bladder. The result had been less getting up at night, amelioration of all the symptoms, and reduction of the residual urine to a half-ounce. In his opinion this was very well worth trying on all cases before adopting catheter life. In locomotor ataxia in which early symptoms of bladder difficulty manifest themselves, the intelligent carrying out of the principles of using the voluntary muscles for expulsion of the contents of the bladder will often delay the commencement of the use of the catheter for many years. It called for intelligent, faithful regular effort, instead of laziness, indifference and ignorance on the part of the patient, and if begun before profound bladder changes have ensued, much good can commonly be expected.

A. Bruce read the autopsy report of a case of complete paralysis of the upward and partial paralysis of the downward movements with conservation of the lateral conjugate deviation functions of the eye. This is a very rare affection, while its converse is common, namely, loss of the conjugate deviation while the upward and downward motions persist. The sixth nucleus innervates directly the external rectus of its own side and indirectly the internal rectus of the opposite ball and is so isolated from the third and fourth nuclei as to render focal lesion of it possible and common. But to have it escape while the other two are destroyed is very rare and pathologically curious. This patient was a hard-working woman, who was overtaken with absolute inability to turn the eyes up, very slight power to look down, while sidewise coordinated function was perfect and convergence, at first perfect, also gradually failed; remarkable unsteadiness in gait and inability to stand erect or sit up in bed without support were present. Ferrier stimulated the anterior part of the middle cerebellar lobe and obtained backward movement of the head and upward turn of the eyes, irritation of the posterior part caused the eyes to be depressed and the head carried forward; still farther back appeared to be centers for the conjugate deviation of the eyes. The post-mortem showed a glioma arising in the grey matter, growing backward along the aqueduct of Sylvius, upward into the third ventricle, sparing the sixth center and accommodation, situate in the midline, projecting into the back part of the third ventricle and not arising from the optic tract.

A. James said that when influenza attacks the nervous system almost any effects may be expected. In his ward three cases of profound influenza poisoning had showed a rapidly ascending paralysis (Landry's type). The following is the history of a clear case: Female; twenty-three years old; attacked by influenza seven months and again two weeks before admission during the activity of the disease; pains in the head and back; delirium; insomnia; periods of rational consciousness; globus hystericus. Physical examination on January 31, 1900, showed temperature 103° F., pulse 130, respiration 22; inability to answer questions; persistent outcry of pain; paralysis of arms and legs, not of diaphragm (as far as could be ascertained); normal sensorium; absence of superficial and deep reflexes; marked impairment of deglutition; Cheyne-Stokes respiration when awake, normal when asleep; slight paresis of upper lip later; complained of pain behind the sternum. Death ensued in the midst of an attack of wild delirium and clonic spasm of the head. In short, the course was one of a rapidly ascending and finally of a fatal bulbar paralysis.

Fleming read the following autopsy notes of the above case: Viscera normal except incipient broncho-pneumonia at the base of the left lung, cloudy swelling of the liver and kidneys, hemorrhage into the spleen. The cerebrospinal system showed firm posterior adhesions of the dura mater; normal pia and arachnoid; general congestion and edema of the grey cerebral matter; no degenerations in the cord-columns; disappointing almost negative lesions in the cord-cells; swelling of medulla-cells and the cells of the anterior cornua; eccentric nuclei and considerable chromatolysis in these same cells; marked atrophy and deep staining of the lumbar and cervical anterior horn-cells with microscopic red blood-cell diapedesis about them, like minute hemorrhages.

N. Walker brought before the society two late syphilides which were instructive from the standpoint of diagnosis. In the first case the decision lay between late syphilis, lupus erythematosus and lupus vulgaris. These points made the diagnosis clear although the site was over the nose, a small punched-out ulcer, rapid development within six months, history of secondaries and results of treatment. The other patient was a nine-year-old child with large nummular masses over the left half of the body and thigh; when these came away large punched-out syphilitic ulcers remained. The treatment was only the tying-on of a large bib to maintain mercury in apposition with the skin.

W. Russell presented a male, fifty-eight years old, victim of myxedema, a disease more rare among men than among women. Complete baldness established through three years; incipient alopecia of the whiskers and beard; mental lethargy; slow speech; malar flush and swollen eyelids were all present.

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Thirteenth Annual Meeting, Held at Louisville, Ky., September 18, 19 and 20, 1900.

First Day—September 18th.

The Association met at the Galt House under the presidency of Dr. Rufus B. Hall of Cincinnati, Ohio.

Dr. Lewis S. McMurtry of Louisville welcomed the Association on behalf of the local medical profession. The address of welcome was responded to by President Hall.

Bilateral Inguinal Celiotomy.—Dr. A. Goldspohn of Chicago considered the erroneous objections to bilateral inguinal celiotomy and shortening of the round ligaments via the dilated internal inguinal rings, and its superior ultimate results in simple and complicated aseptic retroversions of the uterus. For a description of the technic of his operation, the writer referred to his previous articles on this subject. He laid stress upon cutting only through the skin and fat and making the required opening through the aponeurosis, the canal and the internal ring bluntly. The ring is very readily dilated sufficiently to admit one or, if needed, two fingers, and to admit of drawing out the tube and ovary for the exercise of the highest degree of delicate and exact conservative surgery upon them without doing violence to their supports. The wound is closed in four layers *à la* Bassini. In the second layer the round ligament becomes placed as in a sandwich between the posterior surface of Poupart's ligament and a good bundle of elastic muscle at each stitch which makes hernia impossible, and saves the ligament from strangulation while it holds firmly enough against Poupart's ligament to secure a broad union. This hernia has not followed the writer's operation in fully 125 cases that he has examined or had reports from. As the internal inguinal ring is just in front of the normal lateral location of the ovary and ampulla of the tube, these organs and the posterior surfaces of the uterus can be reached by one finger in a one-inch opening here as well as by two fingers in a two-inch opening in the linea alba midway between the symphysis and the umbilicus, and for the necessary access to the pelvic wall to shorten the proper suspensory ligament of the ovary and tube, this small opening serves well; while a large median ventral incision and much traumatism of viscera by that route would be needed, and by the vagina it cannot be done at all.

round ligaments are always present if the uterus is. In fully 190 cases, including 75 simple Alexanders, he has found both ligaments in each case after his pupilage on about one dozen dead women. But in four patients he traced one from within the pelvis outward. He has never had a death from the operation. But one case died from a serious renal complication that was not previously discovered, owing to an exchange of samples of urine by a nurse. Thorough shortening of the round ligaments via their natural channels and anchoring forward (not laterally) is the only operation that has been proven, or is likely to be proven, to stand what the writer demands as the normal standard for all operations of this kind, and has called it the "double test of pregnancy," *i. e.*, that they do not embarrass gestation and complicate labor, which is the single test, but also do not permit a recurrence of retroversion of the uterus after one or more subsequent labors. The difficulties in diagnosis as to presence of pus are no more than proficient gynecologists will meet successfully, and doubtful cases can be cleared up by ten to fourteen days in bed with temperature douches and extensive fomentations. The scars being in the groins, and covered mostly by hair, are not seen like regular laparotomy scars. In the discussion, Dr. Charles G. Cumston of Boston said that from his experience in operating both by the abdomen and vagina, as well as from a pathological standpoint, it has always seemed to him that serious lesions of the adnexa, such as the essayist had treated through a bilateral inguinal incision, are usually out of reach, and that these lesions can be dealt with more easily and satisfactorily through a median, a posterior, or anterior vaginal incision. Simple, uncomplicated cases of retroversion are rare. The Alexander operation in the so-called simple cases of retroversion can be greatly improved by an additional operation through the posterior cul-de-sac. Dr. J. Henry Carstens of Detroit, Mich., rarely sees cases of plain, uncomplicated, non-adherent retroverted uteri that require the Alexander operation. The complicated cases of retroversion require some other operative procedure. Dr. W. E. B. Davis of Birmingham, Ala., referred to the indications for performing the Alexander operation, and called attention to the class of cases in which it should be performed. Dr. Frederic Coggshall of Boston has performed over a hundred Alexander operations in combination with some other operative procedure. In simple, uncomplicated cases of retroversion of the uterus the organ can be easily replaced. Dr. Rufus B. Hall of Cincinnati thinks that the old operation of anterior fixation or ventrosuspension of the uterus is not as popular as it was a few years since. Soon it will only be done in rare instances. He believes, however, that a modified operation, such as that advocated by the essayist, is based on rational surgical principles, and thinks that the author is working in the right direction.

Round Ligament Ventrosuspension of the Uterus.—Dr. D. Tod Gilliam of Columbus, Ohio, said that various devices have been resorted to for restoring and holding in place the retrodis-

placed uterus. All of these have been faulty and many absolutely prejudicial. The need of the hour is an operation that will utilize the natural supports of the uterus, that will insure a fair amount of mobility, that will adapt itself to the various functions of the uterus—pregnancy and parturition, and that will be lasting in its results and withal easy of execution. Profiting by the work of Ferguson along this same line, he has devised an operation which he thinks fulfils all these indications, and, as he believes, solves the problem most satisfactorily. The steps of the operation are as follows: (1) A median abdominal section, three or four inches in length, is made at the usual site between the umbilicus and pubis. (2) The adhesions are broken up and the fundus brought forward, after which the patient is placed in the Trendelenburg position. (3) Seize the round ligament on one side and bring it to the opening. This may be done either by the fingers or by the aid of forceps. (4) Carry a thread under the ligament at a distance of about one and a half inches from the uterus. The free ends of the thread are brought out of the abdomen and secured by clamp forceps. (5) The other round ligament is secured in the same way. (6) Expose the rectus muscle near the lower end of the incision by retracting its sheath and by rolling it out of its sheath on the tips of two fingers applied to the peritoneal surface under it. (7) Select a point one inch external to the margin of the incision and something over an inch above the pubis through which the perforating forceps specially devised for this purpose are thrust into the peritoneal cavity. The two fingers already in the cavity guard the instrument in its passage and place the thread which surrounds the ligament within its jaws. (8) The perforating forceps are now withdrawn, after removing the clamp forceps from the thread, and both thread and ligament are brought up through the perforated wound in the abdomen. (9) While the ligament is held taut, fasten it into the wound by a to-and-fro catgut suture passed deeply through the ligament and including the tissues on either side. (10) Treat the opposite side in the same manner and close the median abdominal incision. Rigid observance of all the rules of aseptic surgery is essential to prevent suppuration, and only a small loop of the ligament should be drawn up through the wound.

Composite Teratoma of the Ovary.—Dr. W. E. B. Davis of Birmingham, Ala., presented a specimen, saying he was in doubt as to the nature of the tumor which he presented, notwithstanding the fact that the above diagnosis was made by pathologists of high standing. Mrs. N., aged thirty-four years, married, was referred to him by Dr. E. G. Givhan of Montevallo May 3d. Mother of three children; had always menstruated regularly. Patient noticed a growth in the abdomen two years ago. She had menstruated in January before the growth was noticed and then missed her periods until March, at which time she menstruated or bled very freely for two weeks. She then missed periods until the following October, with no untoward symptoms except an attack of colic in August. The movements were noticed before August. After October she menstruated regularly until the following January, missed her periods then until October 24, 1899, when a child was born. She has not menstruated since. After the birth of the child at term, the tumor developed quite rapidly and on May 7, 1900, she was operated upon. Patient was discharged as cured June 9th. The tumor was quite large and had a pedicle nearly two inches in breadth and quite thick which was attached to the uterus. The fetus was so large and so well formed that the essayist was of the opinion that there had been an ectopic gestation, with rupture of the gestation sac and the expulsion of its contents into the cavity of a preexisting ovarian cystoma. From the history of the case the diagnosis had been made of an old ectopic pregnancy. He is still inclined to that opinion. Examination reveals a large, rounded, ovoid mass about the size of an adult head, covered by a moderately thin fibrous capsule. The capsule is continuous on one side with the tumor mass. The weight of the whole tumor is 2850 grams. Within the capsule are observed numerous sacs of variable size, which are rounded in contour and filled with a semi-fluid, gelatino-albuminoid tissue. Lying in one side of the tumor is part of a fetus. There are numerous bones of a fetus lying in the capsule. The upper part of the fetus is embedded in the solid portion of the tumor. This portion of the fetus is so intimately combined with the tumor that no sharp line of demarkation can be determined, one tissue gradually passing over into the other. There are numerous nodular and teat-like elevations, in some places covered by smooth skin (?), in others by skin(?) provided with fine, brownish, silky hair. Incision of these frequently reveals a whitish, cheesy substance resembling sebaceous secretion. The soft parts of the fetus are macerated and quite soft. The bones, such as the vertebræ, ribs, tibiæ, and metatarsal, are exposed in many places. There are two well-developed scapulæ (right and left), and to the left is attached some slight semblance of an extremity. Lying in a mass of muscular tissue to the left of the vertebral column is a long piece of bone resembling somewhat a humerus. Attached to the lower end and left side of the vertebral column by means of a flattened piece of bone is an almost perfect lower extremity. The femur is entirely covered by muscle, but the tibia is exposed at its lower end. Some of the phalanges are missing, but the foot is fairly well formed. Careful dissection of the upper part of the fetus fails to reveal any cranial bones attached to the vertebral column. There are two pieces of jaw-bone (inferior maxillæ) lying in the mass of tissue at this

place. They are well shaped, and a dissection of the right one shows rudimentary tooth sacs and a piece of nerve. The laminæ of the vertebræ have not united, so that the spinal canal is not complete and the spinal cord is seen lying in this position, with nerves arising regularly from each side. The bones lying free within the capsule are two parietal, an occipital, two pieces of frontal, abnormally united, several well-formed ribs, and five or six long bones of extremities. Parts of the lungs, liver, stomach, and about sixty centimeters of intestine are preserved.

Microscopic Examination.—Microscopic examination of sections of tissue selected from all portions of the tumor shows a very complex histological structure. Some portions of the tissue are composed of simple, fully-developed adipose tissue, enclosing occasional bands of unstriped muscular tissue, the whole surrounded by fully-developed and practically perfect skin. The skin contains sebaceous and sweat-glands in considerable quantities, and hair-follicles, with hairs in position. The sebaceous glands are larger than those found in normal skin. Other portions show true myxomatous tissue, still others cartilage, and the early stages of osseous development. Sections from the walls of cysts show the inner surface of them to be lined by almost true skin; the epithelial layers lie internally, lining the cyst, the papillary portion lying externally. Sebaceous and sweat-glands occur in these sections and frequently they may be seen opening into the cysts. Other cysts are lined by a simple layer of low cubical epithelium, either in uniform arrangement or thrown into folds or villi, similar to the formations found in uncomplicated cystic papillomatous adenoma of the ovary. The lining of other cysts is made up in some parts of flat or squamous epithelium, in other parts by columnar or cubical epithelium, of the glandular type, and frequently one kind of epithelium passes over into the other. Anatomical diagnosis: Composite teratome, combined with cystic adenoma of ovary.

Chronic Cystitis in the Female.—Dr. Charles Greene Cumston of Boston drew the following conclusions: (1) Sublimate instillations will often produce a very great improvement in the distressing symptoms met with in both tuberculous and non-tuberculous cystitis. In some cases a complete cure may be had. (2) When the instillations fail to produce the desired effect, curettement of the bladder is indicated in both tuberculous and non-tuberculous cystitis. (3) In gonorrheal cystitis instillations of sublimate are very efficacious. (4) Under favorable circumstances a radical cure of primary tuberculous cystitis may be obtained by curettement when the vesical lesions are localized and the kidneys free from the disease. Curettement per urethram will not allow the surgeon to reach the entire surface of the bladder, so that when the lesions are extensive they should be directly treated by suprapubic cystotomy. (5) Much relief may be afforded to a large number of patients suffering from tuberculosis of the bladder, but who on account of the advanced stage of generalized infection are in no condition to undergo a more radical operation. (6) When cystitis is due to a prolapsus of the genital organs, and when hysteropexy, combined with anterior and posterior colporrhaphy, does not relieve the bladder symptoms, curettement of the bladder, followed by sublimate instillations, is the proper treatment.

Dr. A. Goldspohn does not believe that infiltrations, etc., of the bladder can be recognized by the curette at an early stage of the disease process. With this instrument the operator cannot detect beginning ulcerations or papillomatous growths in this organ. The bladder being a membranous organ, curettement of it is entirely different from that of the uterus, in that the operator does not receive the tactile information or intelligence from this instrument in the bladder that he obtains from it in curetting the uterus. Scraping the bladder, therefore, is done largely at random, without any touch sensation to govern the operator as to how little or how much surface he shall curette. Under such circumstances it is not rational to assume that the mucous lining of the bladder will be evenly and uniformly curetted. Uneven surfaces or small areas would be left untouched. In the treatment of infectious cystitis, not tuberculous, he has obtained good results from a solution of one-half to one per cent. of oil of cloves in water. Dr. J. Henry Carstens agrees with the last speaker that there are certain points in the bladder in the class of cases under consideration that cannot be reached by the curette. He has had cases of tuberculous, gonorrheal and septic infections of the bladder which have yielded to the judicious application of permanganate of potash. Dr. James T. Jelks concurred in the statement of Dr. Carstens that permanganate of potash is an invaluable remedy for infective disease of the bladder, particularly of the gonorrheal variety. A solution of 1-6000 is strong enough to begin with, the strength being increased in accordance with the indications of the particular case. Dr. T. J. Crofford of Memphis has performed curettage of the bladder several times. If the inflammatory process is confined to the neck or thereabouts, there is very little difficulty attending the curettement of that area of surface. No inflammatory zones would be left to cause further trouble. Dr. Cumston in closing referred to the pathology of bladder lesions and said they were almost always situated in the trigonum, consequently this is the portion of the viscus which the operator should strive to reach. If the whole bladder surface is involved, suprapubic cystotomy is the operation of choice, and curettement in such a case would do very little, if any, good. He uses the cystoscope in the treatment of this class of cases.

Perforated Gastric Ulcer with Remarks.—Dr. Henry Howitt of Guelph, Ontario, read this paper. The first two cases occurred years ago before the operative procedures were commonly known and had the usual termination, one dying within twenty-four hours from the commencement of the illness without having had a single symptom indicating the existence of the trouble. The other two reported by him are of recent date and the patients were saved by timely operations. In one the operation was devoid of any serious difficulty, but in the other the abdomen contained gas and a large amount of pus, the colon was enormously distended, requiring to be opened, and collapsed before the stomach could be reached. There existed also the remains of a ruptured abscess cavity below the transverse portion of larger bowel, the walls of which were formed by it together with the coils of small intestine and omentum. This had its origin probably in a slight leakage which occurred days before the final rupture. The orifice of the ulcer was of sufficient caliber to admit his little finger, and was situated in front close to the pyloric valve. The surrounding parts were so thickened, dense and nodular as to exactly resemble carcinoma of the pylorus and adjacent part of the stomach. A section nearly two inches in length had to be removed before the ulcer could be closed. The intestines were previously eviscerated to permit of the room necessary to reach the part and to expose the pools of pus in the pelvic flanks and other places difficult to reach. The upper portion of the jejunum was anastomosed by means of a Murphy button to the anterior wall of the stomach. After the anastomosis was completed, the arm of intestine above was stitched to the wall of the stomach an inch or more to the right and a little above the line of the button. This procedure in his opinion overcomes the acute angle and its ill-effects. Drainage-tubes were inserted through perforations made in flanks well to the back and in the lower abdomen close to the pelvis, to the outer side of the right rectus muscle. The sutures were all removed except two in the middle of the wound opposite the umbilicus on the seventh day. Three hours later the patient had a sneezing fit, and the wound tore open from the upper angle to the umbilicus, exposing the situation of anastomosis, and coils of bowel protruded. It was restitched an hour later without anesthesia, and no ill-effects followed. The patient made an uneventful recovery, and is now for the first time in eighteen years free from gastric distress.

Dr. W. E. B. Davis has never operated for ulceration of the stomach, attended by perforation. He had encountered two cases which he should have operated upon had the symptoms been sufficiently marked to warrant operative procedure, but they were not, and he did not feel therefore emboldened to undertake it.

Dr. Edwin Ricketts narrated the case of a woman, forty-eight years of age, who had had a gastric ulcer for three years. Under rectal alimentation she gained sixty pounds in flesh. Subsequently she committed some indiscretion in diet, was again taken sick, and consulted another physician, who made a diagnosis of cancer of the pylorus. She went from bad to worse, and finally died. Post-mortem examination revealed a perforating gastric ulcer the size of a lead pencil, situated on the anterior surface near the pylorus. Dr. A. Vander Veer of Albany spoke of two cases of gastric ulcer which ultimately resulted in carcinoma of the pyloric end of the stomach. From the number of cases in which he has done gastrointestinal anastomosis, he is satisfied that he has had to deal with the cicatrices resulting from gastric ulcers in many instances.

Surgery of the Gall-Bladder.—Dr. A. Vander Veer of Albany said that no great reliance is now placed upon jaundice as a positive symptom. Four interesting and instructive cases are reported and the following conclusions drawn: (1) An early diagnosis is important. (2) In suppuration of the bladder with adhesions, a most thorough examination should be made from within by digital exploration and use of the probe for any possible deep-seated calculi. (3) In prolonged operations upon the common duct or hepatic ducts, where adhesions are present and it is difficult to close the incision after removal of the calculus, drainage through the peritoneal pouch by means of the lumbar stab is advisable. (4) When the patient is suffering seriously from cholemia, with marked ecchymotic spots over the body, intense itching, the blood examined, and found in a septic condition, an operation is not to be encouraged. (5) General practitioners as well as the surgeon should place more earnestly before the patient and friends the dangers of repeated attacks of gall-stone irritation resulting in cancer of the ducts, stomach or liver.

[To be continued.]

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 3, 1900.

The First Vice-President, William H. Katzenbach, M.D., in the Chair.

Hyperchlorhydria.—Dr. Max Einhorn said that some fifteen or twenty years ago it was held that disturbances of the stomach were generally supposed to be conditions in which the secretions were deficient. When dyspepsia was present hydrochloric acid was always given to supplement the secretions. Later investigations and study of the gastric secretions in normal and diseased states showed that the secretion of hydrochloric acid might be above normal in pathological conditions. This was thought to be exceptional, but statistics have shown that the percentage of the cases of increased secretion is

not small. It was found that conditions existed in which secretion continued even when there should be none at all, that is in an empty stomach. The speaker said that he did not wish to take up the whole subject of hypersecretion, however, but merely that of hyperacidity.

Proportion of Cases of Hyperchlorhydria.—Dr. Einhorn has tried to learn the proportion of cases of hyperchlorhydria to general digestive ailments. In two years' experience he finds that half his patients show a greater degree of acidity than normal. Moreover, the proportions are not alike in every city. In the smaller cities and towns the cases of hyperchlorhydria become less and less in number. In the country they are almost unknown. It is characteristically the disease found among the so-called better classes, the business man, the man of many cares, the intellectual man, women who are active socially and intellectually. This explains to a certain extent the discrepancies between the large cities and the smaller places in the statistics of this disease.

Characteristic Symptoms of Hyperchlorhydria.—The hyperchlorhydria may be recognized not only by an examination of the gastric contents, but by clinical symptoms and the general appearance. The patients are usually well nourished, plump, and appear in good condition. Only exceptionally a run-down case presents itself. They suffer from pain an hour or two after eating, the immediate effect of the taking of food being a feeling of relief. Sometimes this feeling of distress and pain occurs only after certain meals. For instance, the patient may be well after breakfast and luncheon but suffer after dinner—the heaviest meal of the day. A number of cases find that they are relieved after belching up gas. Others have a dulness over the pit of the stomach and occasionally suffer from water-brash. Another and smaller group complains of regurgitation. Some have a burning sensation along the esophagus, but nothing comes up. There are again rarer cases in which there is no pain, but in which there is complaint of dizziness one to two hours after meals, or of a feeling of fright at that time. That this dizziness and fright are due to hyperchlorhydria is proved by the fact that they disappear with treatment for that condition. Sometimes hyperchlorhydria may be mistaken for genuine angina pectoris, the symptoms are so much alike, there being dizziness, fright, a little difficulty in breathing and pain in the precardia. Sometimes there are no stomach symptoms, but severe headaches an hour or two after meals. These, too, disappear with treatment for hyperchlorhydria. In 90 per cent. of the cases where the symptoms indicated are present hyperchlorhydria may be assumed. In rare cases achylia gastrica, where there is no juice at all, may present the symptoms of hyperchlorhydria.

Anomalous Symptoms.—The appetite is usually good and the food is taken with relish. A small fraction has a hungry feeling an hour or two after eating and at other unnatural times. The thirst, however, is not increased. The bowels are nearly always irregular. Some suffer from obstinate constipation, which increasing doses of cathartics do not allay, though this constipation disappears with treatment for hyperchlorhydria. A smaller proportion, perhaps 5 per cent., suffer from diarrhea. There are cases, however, in which a positive diagnosis can only be made by an examination of the contents of the stomach.

Hyperchlorhydria Without Symptoms.—Hyperchlorhydria may exist without giving rise to symptoms. Dr. Einhorn has had patients in whom the symptoms ceased entirely, yet an examination of the stomach-contents later showed the hyperacidity to be just as great as ever. In such cases, outside of care of the diet, there should be no treatment. Sometimes hyperchlorhydria seems to be an anomalous condition of the stomach normal to a particular individual.

Causes of Hyperchlorhydria.—It has been thought that hyperchlorhydria is due to some anatomical lesion, but as the disease does not have a fatal termination there could be no autopsies and there was much speculation with regard to its morbid anatomy. Hansemann had a patient suffering from hyperchlorhydria who died suddenly of pneumonia. The stomach was found to be normal. The mucous membrane was examined microscopically, but no lesions were found. Dr. Einhorn personally has examined small pieces of the mucous membrane of living patients, and has found strongly hypertrophied glands, but every organ that is overworked hypertrophies, and this condition of the mucous membrane must be looked upon as a secondary, not a primary condition. Dr. Einhorn thinks hyperchlorhydria a functional disease, the disturbance in the secretions being due to nervous derangement, as is shown by its prevalence among the classes subject to nervous worry and strain and excitement. Besides the nervous influences, to a slighter degree tobacco or alcohol or both may contribute to the disease.

Hyperchlorhydria and Ulcer of the Stomach.—Hyperchlorhydria exists in ulcer of the stomach. It is a matter of controversy whether the mucous membrane in case of ulcer is more vulnerable and excited, or whether the ulcer is the cause of the hyperchlorhydria. Dr. Einhorn does not think that the ulcer is the cause, as he has found ulcer of the stomach in which there was subacidity or no acidity at all. It may be said to be true, however, that where there is chronic hyperchlorhydria ulcers develop more easily.

Differential Diagnosis.—In the diagnosis of hyperchlorhydria it is sometimes difficult to distinguish between hyperchlorhydria alone and the disease in connection with other pathological conditions. There may be an ulcer or gall-stones may be present and the symptoms be similar to mere hyperchlorhydria. If there is vomiting of blood, pain occurs immediately after taking food and the area of pain is circumscribed: it is probable that there is an ulcer in addition to the hy-

perchlorhydria which an examination of the contents of the stomach will show. The evidence of the presence of an ulcer may be found in the resistance of the conditions to treatment for simple hyperchlorhydria. In a case of hyperchlorhydria which does not yield after three or four months of treatment the conclusion that there is an ulcer is perfectly reasonable. Hyperchlorhydria also frequently exists in connection with gall-stones. In the attacks due to gall-stones the pain comes on very suddenly and is extremely severe. They are not dependent on meals. These symptoms make the differentiation of gall-stones from ulcer easy as a rule. Certain cases will however present serious difficulties.

Treatment.—Dr. Einhorn finds it very satisfactory as a rule to treat hyperchlorhydria. It is a condition which yields with gratifying readiness to rational therapy. Diet is of course the most important consideration. There was a time when physicians prescribed meats, little fat, no carbohydrates, no starchy foods, the reason being that starchy foods irritated the stomach and were not digested in the presence of an excess of acid. This exclusive meat diet is being abandoned, however. Starchy foods have an important part in the sustenance of the body and, moreover, their effect in the stomach is not so serious as was thought, for their digestion depends very largely upon the intestinal juices. Partly for this latter reason just the reverse of the exclusive meat diet has also been held to be the right thing. Because meat increases the gastric secretions it has been excluded entirely by some in the treatment of hyperchlorhydria and starchy foods only have been given with a little milk. Dr. Einhorn finds a medium course between these extremes the most satisfactory. It is not safe to deprive people of so important a group of foods as the starches in a treatment which must be kept up for months, sometimes for years. Dr. Einhorn tries to limit the indulgence in the foods that seem most irrational and prove to be irritating, but does not entirely exclude anything except acids. He permits the patient to have meats, preferably the tender kinds and those not too highly seasoned, milk, bread, butter, and sugar. Of the starchy foods he particularly restricts potatoes. The acids can safely be eliminated as they supply no element of nourishment. He directs the patients to eat smaller meals and to eat oftener. In this way the energy of the stomach is saved. The food relieves the symptoms for a time, because the albumin in it takes up the acids and so checks the effect of the hyperacidity on the mucous membrane. He insists that the patient eat bread and butter, or a bowl of milk and bread, between each meal, and if the hour for retiring is late a bowl of milk and bread before going to bed, in order to avoid waking up hungry and uncomfortable during the night. He objects to any food that is highly seasoned. Recent experiments have shown that sugar has a tendency to diminish acidity and sugar may therefore be taken with safety. The fats, cream and butter are especially beneficial in reducing acidity.

Medicinal Treatment.—The alkalies should be given at the time when the acidity is highest, about two hours after meals. Bicarbonate of soda, given in doses of one-half to one teaspoonful, gives good results. For the constipation, rhubarb and soda, or rhubarb and magnesia may be given; if there is diarrhea instead of constipation the soda only should be given. The bromides are useful along with the alkalies where there is a nervous and excited condition. Dr. Einhorn does not approve of belladonna or atropine. The disease requires remedies which can be given with safety for long periods of time. The washing out of the stomach is not essential. He prefers to spray the stomach with nitrate of silver, as in this way a smaller amount of the drug can be used and it is not necessary to get it out again, as is the case when the stomach is washed. He finds the use of the electric current beneficial. The faradic as well as the galvanic current should be used.

REVIEWS.

Transactions of the New York State Medical Association. For the Year 1899. Volume XVI. Published by the Association.

This volume of Transactions contains several series of articles that it is well worth practitioners' while to know where they may be obtained for reference. There is a discussion on expert evidence containing articles by such well-known legal authorities as Justice Bartlett of the Supreme Court, ex-Judge Joseph Daly of New York, Charlton T. Lewis, Esq., William A. Purrington, Esq., and Theron A. Wales, Esq.

The feature of the volume, however, is the discussion on typhoid fever, which occupies nearly 150 pages. The various phases of the subject are presented by such distinguished specialists as Dr. William Osler of Baltimore, Dr. W. H. Thomson of New York, Dr. Reginald Fitz of Boston, Dr. A. A. Smith, Dr. Abraham Jacobi, Dr. E. G. Janeway, Dr. Herman M. Biggs and Dr. William H. Park of New York. The surgical aspects of the disease are presented by Dr. W. W. Keen of Philadelphia. On the whole, it may be said of this volume that it is one of the best representatives of thoroughly scientific work issued by any of the State Medical Associations in the country.

Report of the Mortality Records of the Mutual Life Insurance Company of New York for Fifty-six Years (1843 to 1898). By Elias J. Marsh, M.D., and Granville M. White, M.D., Medical Directors. New York: The Mutual Life Insurance Co., 1900.

This report will be read with interest by those who have to do with life-insurance examinations

as well as by those who are concerned for anthropological reasons with the percentages of deaths at different ages. In the first table presented it is seen that under forty-five years of age, the greatest incidence of mortality is from tuberculous disease, there being 3307 deaths from consumption out of a total of 13,623; between the ages of forty-five and sixty apoplexy and arterial diseases lead in the causes, with digestive diseases next and consumption and heart disease important factors; above sixty years of age the cardiac diseases and arterial disturbances overbalance the other causes of death, as one would expect. Bright's disease, according to this table, kills about an equal number of persons in the periods between forty-five and sixty and above sixty years of age. The acute infectious diseases are prominent factors of death below forty-five and appear to be equally virulent above sixty, while between these years their mortality is not so high.

Eighty-one deaths are reported as due to abortion and puerperal diseases, although the tables do not state the actual cause of death, whether sepsis, convulsions or other puerperal complications. The majority of these deaths occurred within the first year in which the policy was issued and for this reason the company does not solicit for insurance pregnant or newly-married women.

There are thirty-five tables presented in which the mortality is shown in different States and countries, in different diseases at different ages, age percentages, disease percentages, etc. The work is monumental and is carried out along the lines of the Bertillon system. It is interesting as a study and useful as a reference work.

Atlas and Epitome of Special Pathologic Histology. By Docent Dr. Hermann Dürck, Assistant in the Pathologic Institute, Prosector to the Municipal Hospital in Munich. Authorized Translation by Ludwig Hektoen, M.D., Professor of Pathology in Rush Medical College. Volume I. Circulatory Organs, Respiratory Organs, Gastro-intestinal Tract. With 62 colored plates and 158 pages of text. Philadelphia, W. B. Saunders, 1900.

After a brief review of the normal histology of an organ, the author compares the pathological condition of this with that of other organs or of the whole body, and then cites the etiology of the individual cell-changes, and describes the microscopical appearances of the various cut sections. These latter are illustrated as ordinary stained microscopical sections, two or more appearing on each colored plate. Their distinctness of delineation and accuracy of coloring is a credit to the publishers. This volume includes the heart, pericardium, vessels, lymphatic glands, spleen, bone-marrow, nose, larynx, trachea, bronchi, lungs, pleura, thyroid, mouth, pharynx, esophagus, salivary glands, stomach, intestines and peritoneum.

Food for the Sick and How to Prepare It. By Edwin Charles French, M.D. John P. Morton and Company, Louisville, 1900.

This little volume is a very useful and practical collection of recipes that have been gathered from the head-nurses of hospitals all over the country. Some of them are said to be contributed by well-known physicians. None of the recipes are to be found in the ordinary cookbook and each recipe is said to have been thoroughly tried by a competent cook. The volume is calculated to be of the greatest assistance to those who have the care of convalescents. Its perusal cannot but prove suggestive to physicians as a guide to the directions they may give for the feeding of patients.

A Manual of Obstetrical Technique as Applied to Private Practice. With a Chapter on Abortion, Premature Labor, and Curettage. By Joseph Brown Cooke, M.D., late Attending Physician to St. Mary's Free Hospital for Children, Out-Door Department; late Attending Physician to the Northwestern Dispensary, Department of Diseases of Children, etc. Philadelphia and New York: J. B. Lippincott Company, 1900.

This little book is exactly what the title indicates it to be and what the author intended it should be—a manual describing in detail the technique of caring in private practice for a pregnant woman during the whole course of her pregnancy. The subject is considered solely from the standpoint of a physician treating a private case in her own home, and shows very clearly that such cases, with a little care and forethought, can be treated as well in private households as in a well-appointed lying-in hospital, no matter what emergency may arise. The key-note of the whole thing, of course, is to be thoroughly aseptic and to be ready for any emergency. How to be always aseptic and always ready the author tells in detail. He describes how the lying-in chamber should be prepared, and also the physician's outfit. This outfit consists of two distinct parts, the obstetrical box which is sent to the patient's house two or three weeks before labor is expected, and the obstetrical bag which the physician takes with him to the case. The details of every step in normal labor, and also in forceps delivery, version, craniectomy, perineorrhaphy, trachelorrhaphy, and symphysiotomy are described. Asepsis and antisepsis are vigorously insisted upon in every procedure.

The author makes numerous suggestions which many general practitioners might well adopt. To young practitioners just beginning, for whom the book is intended, it will prove of value, as every detail in the conduct of a case of pregnancy, from the initial visit and examination at the beginning of pregnancy to the delivery of the child and the convalescence of the mother, is carefully and minutely described.

The book is written clearly and concisely, and touches upon all those "little things" which go to make up the important whole, but which are not usually mentioned in text-books and which the young practitioner usually has to learn "by experience." The volume is illustrated by numerous excellent photographs of the different methods of examination and delivery of the pregnant woman.

Diseases of the Eye. By Edward Nettleship, F.R.C.S., Ophthalmic Surgeon to St. Thomas' Hospital, London; Surgeon to the Royal London (Moorfield's) Ophthalmic Hospital. Revised and Edited by Wm. Campbell Posey, A.B., M.D. Sixth American from the Sixth English Edition. Small 8vo., pp. 560. Lea Brothers & Co., Philadelphia and New York, 1900.

Nettleship's text-book has long been recognized as one of the best of the smaller text-books on the eye, and the present edition is considerably augmented and brought up to date, while the introduction of a number of special features considerably enhances the value of the work.

Normal Histology. By Edward K. Dunham, M.D., Professor of General Pathology, Bacteriology and Hygiene in the University and Bellevue Hospital Medical College. New Second Edition. Lea Brothers & Co., Philadelphia and New York, 1900.

Dr. Dunham's book on histology has heretofore contained pathological as well as normal histology. In issuing the second edition a change is made that presents the normal histology in a separate volume. The former edition of the book is so well known that the present volume needs no words of commendation. Dr. Dunham's style is eminently concise and clear. It is a distinct pleasure to read his lucid English. Text-books are often couched in a style so lacking in clearness and precision and in a phraseology so labored that the present work appears by contrast to have special merit. Medical writers generally are so little commendable for anything like grace of style that it is to be hoped that the rising generation of medical men influenced by text-books like this shall present what they have to say with less waste of words than has heretofore been the custom. Passages like the following commend themselves as models of terse descriptive writing: "The red corpuscles are soft elastic disks, with a concave impression in both surfaces. They are slightly colored by a solution of hemoglobin and are so abundant that their presence gives the blood an intense red color; but when viewed singly under the microscope each corpuscle has but a moderately pronounced reddish-yellow tinge. The hemoglobin solution is either intimately associated with the substance composing the body of the corpuscles, called the stroma, or it occupies the center of the corpuscle and is surrounded by a pellicle of stroma."

The illustrations in the book have the very praiseworthy quality that they all really illustrate. None of them are introduced merely for the purpose of increasing the number of illustrations in the book without adding any clearness to the text. Altogether there are 244 illustrations to 263 pages of text.

ORIGINAL ARTICLES.

COCAINE ANESTHESIA BY LUMBAR PUNCTURE: TWO CASES OF HYSTERECTOMY.

By J. RIDDLE GOFFE, M.D.,
OF NEW YORK;
VISITING GYNECOLOGIST TO THE CITY HOSPITAL; PROFESSOR OF GYNECOLOGY IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

THE success that has attended the intraspinal injections of cocaine for the purpose of producing anesthesia of the lower half of the body aroused no little enthusiasm at the recent International Medical Congress. Indeed, it was considered one of the prominent advances in surgery worthy of record on that occasion. The credit of demonstrating the advantages of this method of anesthesia in surgery is due to Professor Bier of Kiel, but Tuffier of Paris and Kreis of Bucharest have used it in a greater number and a wider variety of cases. The experience of all these men shows pretty conclusively that the method is successful in producing complete analgesia during operations extending over a period of two hours, and that the benumbing effect of the drug gradually wears off in the course of three or four hours, sometimes continuing a little longer. The immediate effects are no more disagreeable than those of ether or chloroform and are entirely devoid of danger. What remote consequences may develop as the result of such interference with the spinal fluid and the intraspinal pressure that this method involves can only be determined after more prolonged observation. Up to the present time, however, no detriment to the patient has attended the procedure, although observations have extended over a period of two years. The amount of the drug used varies from one-twelfth to one-half of a grain, but the usual dose is one-sixth or one-third of a grain. The analgesic effect extends usually from the toes to the umbilicus and operations may be performed with immunity to pain on any parts below the latter point.

Prompted by the experience of these men and by the success of Dr. Marx[1], of New York, with the method as applied to obstetrics, I have ventured to use it in two cases as follows:

Case I.—Vaginal hysterectomy, August 27th. Mrs. R., aged forty-eight years, the mother of nine children, a widow for the past six years; had both uterine appendages removed by laparotomy three years ago. She has suffered from constant backache and pain since the operation and is not able to work. The heart, lungs and kidneys were found normal and hysterectomy was advised. The patient gladly consented to the use of the new method of anesthesia, when it was explained to her, for she said she had suffered terribly from nausea and vomiting from ether at her previous operation. The patient was placed in the Sim's posture, the body being well flexed, and the skin of the lumbar region was thoroughly scrubbed. The spine of the fourth lumbar vertebra was then located and permanently retained by pressing firmly upon it the ball of the left thumb. The empty hypodermic needle, unattached to the syringe, was then inserted into the tissues on the patient's right just at the edge of the thumb and pushed steadily forward, inward and upward, until the spinal fluid was seen to appear and finally drop from the end of the needle. In this case the needle was forced in to a distance of three inches (it is best to use a needle about four inches long) and fifteen drops of the fluid were allowed to escape. The syringe was then attached and thirty minims of a two-per-cent. sterilized solution of cocaine were injected. In two minutes the patient described a tingling sensation in her feet and legs, and almost immediately insensibility to the prick of a pin appeared in the extremities and gradually advanced until it reached the fourth dorsal vertebra in the back and a point above the breasts in front. There was some excitement on the part of the patient, due partially to the intense interest felt by all in the experiment, the pulse running up to 104 and the respirations to 36. Vaginal hysterectomy was then performed, the angiotribe being used as the hemostatic, the patient being ready for bed in thirty minutes. The crushing of the vessels and nerves by the angiotribe was probably as severe a test of the analgesic effect of the method as could be applied, and yet the patient felt no pain or discomfort, simply reminding me from time to time that I agreed not to cut her, *i. e.*, incise the abdomen. About fifteen minutes after the injection profuse sweating occurred (such as often attends ether narcosis), followed by considerable nausea with slight retching and vomiting. A severe headache came on during the operation and continued until 9 P. M., about ten hours. The patient was conscious throughout the entire procedure, spoke frequently and asked questions. An hour after the operation she said she was more comfortable than at the same epoch in her previous operation. The patient has had a smooth, normal convalescence.

Case II.—Abdominal hysterectomy, August 31st. Miss D., single, aged fifty-one years, suffering from hemorrhages due to multiple fibroids of the uterus. The patient had a hydrocephalic head and a kyphotic pelvis. The patient was placed in the Sim's posture and the back prepared

[1] MEDICAL NEWS, July 28, 1900.

as in the previous case. Owing to the ankylosis of the lower lumbar vertebræ some difficulty was experienced in entering the subarachnoid space and two or three unsuccessful attempts were made. Finally, the needle was introduced in the third lumbar space, the spinal fluid appeared in the needle and one-third of a grain of cocaine was injected. Analgesia was very imperfect and fifteen minutes later the needle was inserted in the second lumbar space, twenty-two drops of spinal fluid were allowed to escape and one-third of a grain of cocaine was injected. Analgesia promptly appeared, reaching above the umbilicus. An incision was made through the right rectus muscle and supravaginal hysterectomy was performed in accordance with my method of covering the stump with peritoneal flaps, the angiotribe being used as the hemostatic on the broad ligaments. The operation occupied forty minutes. The sweating, nausea, vomiting and headache occurred as in the previous case. The vomiting recurred on the following day. In this case the analgesia was not as complete as in the former and recovery from the effects of the cocaine came so promptly that the last manipulations in the operation, the removal of sponges from the abdominal cavity and the sewing of the wound, gave occasional twinges of pain. The recovery has been uneventful.

As fas as I know these are the first operations, aside from the obstetric experience of Dr. Marx, that have been attempted according to this method of anesthesia in this country, and it is quite possible that the abdominal hysterectomy is the first on record anywhere. At least I can find no mention of this operation in the list of surgical procedures reported in Europe, although those lists include vaginal hysterectomies, appendectomies, vaginal sections and herniotomies.

A CONSIDERATION OF FINGER INFECTION WITH SPECIAL REFERENCE TO THE JOINTS AND TENDONS.

By ELLSWORTH ELIOT, Jr., M.D.,
OF NEW YORK;

ATTENDING SURGEON TO THE PRESBYTERIAN HOSPITAL; CLINICAL LECTURER AND DEMONSTRATOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS.

Inoculation of different portions of the body by some variety of pyogenic organism is of frequent occurrence. In certain cases the germ is carried to the affected area by the blood or lymph-channels, although the exact mode of its entrance into the body interior is uncertain; more frequently the inoculating material is introduced directly into tissue space through some abrasion. This obviously is of most frequent occurrence in the extremities, which, from the personal occupation or habit of the patient, are most likely to come in contact with contaminating objects. The fingers, consequently, are particularly subject to wound infection. This predominates in the palmar surface of those most frequently called into use.

The results of such infection depend on the resistance which the body is capable of presenting to the invading germ. In individuals of strong, robust temperament, such a process usually remains circumscribed; in those, on the other hand, of feeble powers, whether from disease, as for example, diabetes, or inherent weak vitality, any infection shows a tendency to become diffuse, involving not only the adjacent surface of the body but spreading more or less quickly to the structures more deeply seated. The course and development of infection depend also on the virulence of the invading germ, as well as on the quantity introduced. If a large number simultaneously enter the body or if the germ is particularly virulent, the resistance presented by even a robust individual may not be sufficient to prevent the rapid extension of the process, and at times the overpowering of the entire system by the toxic products of the pyogenic germ.

Cases of wound infection in the fingers consequently vary greatly in the extent of damage to the structures involved. In the mildest forms the process is limited to the skin and the subcutaneous tissue with but slight if any constitutional disturbance, and results in the necrosis of a limited portion of tissue, which may either be removed by lymphatic absorption or may be discharged from the surface of the body by the progress of suppuration, a rapid recovery ensuing.

In more severe cases, however, access of the pyogenic organism to the tendon sheath takes place; an acute necrotic inflammation fills and distends the sheath with pus, the extent of which depends on the particular sheath involved. The sheaths of the index, middle and ring fingers are separate from the common palmar sheath, and infection involving these sheaths rarely extends beyond the finger proper; on the other hand, the sheath of the long flexor of the thumb invests the tendon in a prolongation, which, occasionally communicating with the common palmar sheath, extends under the annular ligament to the lower part of the forearm. Infection of this sheath is quickly carried along the course of the tendon, and not infrequently extends into its muscle belly. In the large majority of cases, which have come under my notice at the Vanderbilt Clinic and elsewhere during the past ten years, the common flexor palmar sheath, notwithstanding its close proximity to the flexor sheath of the thumb, particularly as they lie under the annular ligament, escapes damage. Infection of the sheath of the little finger is also carried along the prolongation of the sheath of that tendon into the palm, where it involves the common palmar sheath.

On the dorsal surface of the fingers the arrangement of the sheaths of the extensor tendons is irregular and infection is uncommon. In one case of infection of the extensor tendon of the little finger, the process extended to the dorsum of the hand, remaining confined, however, to the original tendon.

No matter what tendon involved, the pathological process is identical. The sheath becomes distended with pus, which impairs both its vitality and that of the sheath; eventually rupture allows the escape of the pus, but only rarely does the tendon escape necrosis. Usually the resulting tendon-slough separates from its viable part above and below, and is discharged from the wound which shortly after heals by granulation, leaving a finger the function of which is permanently impaired. In these cases of tendon infection the germ gains access to the sheath, either directly through a penetrating wound or indirectly through lymphatic channels that open into the sheath. It is therefore possible for tendon infection to develop as a complication of a wound that does not even extend through the subcutaneous tissue.

The clinical aspect of finger infection is, in certain cases, materially governed by the involvement of one of the metacarpophalangeal or of one of the interphalangeal joints. A complication of this nature may result from the introduction of the agents of infection through a wound penetrating the joint or, as is the case with tendon infection, the germ may be carried from the original focus, involving only the subcutaneous tissue, by a lymphatic vessel directly into the joint cavity.

The pathological changes resulting from joint infection are best understood by dividing the process into the following stages: (1) Stage of joint distention. (2) Stage of joint disintegration. (3) Stage of repair.

In the first stage the entrance of the germ is followed by the development of an acute suppurative inflammation, distending the synovial cavity with pus. The articular ends of the bone are the site of an acute ostitis, the extent of which depends upon the severity of the process. In the second stage the capsular ligament yields to the pressure of the accumulated pus within, and allows its escape into the periarticular structures, which it penetrates, reaching the skin in the direction of least resistance through an insufficient orifice. At the same time the inflammatory ostitis has resulted in the necrosis of the articular surfaces, first shown in the complete or partial denudation of the articular cartilage. The advent of the third stage depends on the freedom of joint drainage; in it the necrotic portions of bone, cartilage, ligament and synovial membrane gradually separate from adjacent viable structures and as these discharge from the wound a cavity remains, lined by granulation tissue, into which the extremities of the viable portions of the phalanges project. This cavity gradually fills and heals by granulation. If the above-mentioned bony extremities are placed in contact bony ankylosis results; if they remain apart fibrous ankylosis usually develops. Occasionally the formation of a false joint permits partial restoration of joint movement.

In this group of cases the infection of the joint may be the sole complication of the infected wound, or, and this is not infrequent, the tendon sheath is simultaneously involved. This latter structure may rarely become secondarily involved by the entrance into it of the pus which escapes through the giving away of the capsular ligament of the joint. When the process of repair is complete the destruction of the bone results in a permanent shortening of the finger. In one of the cases reported (*Case IV.*) this took place without the exfoliation of any recognizable fragment of bone. This demonstrates the fact that, after the necrosis of the articular ends, the disintegration of the bone may be so gradual that the process of sequestration is accomplished without the appearance of any bony fragment whatsoever in the dressing.

Pyogenic infection of the extracapsular portion of phalanx or metacarpal bone in conjunction with infected wounds of the fingers occurs only when the original injury has penetrated directly to and involved the bone. It occurs most frequently in compound fractures, where the infection is followed by an osteomyelitis, resulting in a moderate amount of necrosis, the union of the fragments being delayed until the process of sequestration is complete. Occasionally, in the case of infected wounds penetrating to the bone without fracture, a similar process develops which is generally limited to the periosteum and the contiguous superficial portion of the bone.

These different pathological conditions of infected wounds of fingers have been described to emphasize the fact, that, although infection of a joint may be the only complication, it is not infrequently associated with and its clinical picture modified by the infection of the adjacent tendon sheath, while the development of the pathological process in the subcutaneous tissue, always variable, may be so marked as to render the diagnosis of an accompanying joint infection a difficult matter.

The clinical picture of a joint infection is therefore usually complex, and the consideration of its symptoms includes not only those relative to the joint, but also, very frequently, those belonging to an associated tendon-sheath infection, as well as those due to the involvement of the overlying soft parts. As far as the joint is concerned, the symptoms include those of joint penetration and secondly those of joint infection.

The symptoms of joint penetration consist in the observation by the patient or the surgeon of the escape from the wound of synovia in the form of a small amount of tenacious, viscid and glairy fluid, which, at first transparent, becomes with the advent of infection discolored and diminished in quantity and irritates the surrounding parts. With the onset of inflammatory changes, symptoms due to the infection of the soft parts and of the joint cavity develop simultaneously, the former being more prominent and frequently masking the latter.

In the absence of joint complication the infection of the soft parts is marked by pain, most in-

tense over the point of puncture, with redness and swelling, which, most marked over the original area of infection, gradually shades off into the surrounding parts. The simultaneous involvement of the joint alters these symptoms in the following way. The pain is more severe and is usually intensified almost beyond endurance by any movement of the joint no matter how slight. The swelling becomes much more pronounced and involves the entire circumference of the finger over the joint, instead of remaining confined to the location of the wound. That portion of the general swelling which is due to the distention of the joint is more tense and elastic than the remainder, and over the dorsal aspect of the finger, where the overlying tissues are thin the outline of the distended synovial cavity is sometimes plainly visible.

If the infection is limited to the subcutaneous tissue, the active function of the finger is impaired; if the joint is involved, however, there is complete abrogation of its function and any passive movement elicits excruciating pain. These are in brief the local symptoms of joint infection in the stage of joint distention. In addition the patient develops the constitutional symptoms of fever, of which the onset is sometimes preceded by a chill of an intensity which varies with the nature of the infection.

With the destruction of the capsular ligament, the pus, previously confined within the limits of the joint, speedily finds a means of exit, and its discharge is followed by a partial subsidence of the constitutional symptoms, as well as by the following local changes. The swelling in the soft parts practically disappears; the swelling due to the joint involvement is, consequently, more prominent and, owing to the involvement of the articular ends of the bones and their periosteal coverings to which the inflammatory process has extended, is so pronounced that the circumference of the finger at that point is at least doubled. This swelling subsides very slowly as the process of sequestration results in the gradual discharge of the diseased bone.

The destruction of the lateral portions of the capsular ligament furnishes a pathognomonic symptom in the presence of a preternatural mobility, elicited usually without pain by moving the phalanges on each other from side to side. In the great majority of cases this movement produces a crepitus, due to the rubbing together of the roughened articular ends, which have been partially denuded of their cartilage. Its quality is similar to that of the crepitus of fracture. Active function of the joint is lost in this, the stage of joint destruction, although passive movements of flexion and extension may be made without causing marked pain.

Through the sinuses communicating with the interior of the joint a probe may be passed into the joint cavity and with it the roughened denuded area in the articular cartilage may be detected. It also not infrequently reveals the fact that the adjacent portions of the phalanx are bare and very extensively thickened. These areas do not always undergo exfoliation, but sometimes subsequently become covered with granulation tissue, over which cicatrization takes place, the bone, however, usually remains permanently thickened.

During the process of repair the fever entirely subsides and the joint crepitus, as well as the bare roughened bone, disappears, when, after the discharge of all necrotic material, the remaining viable phalangeal extremities become invested with the soft granulation tissue, which gradually fills the original joint cavity. After cicatrization is complete propagation of connective tissue may either connect the bones in fibrous ankylosis, or in favorable cases a new capsular ligament may be formed, enclosing a pseudarthritic cavity, as in *Case II.* In other cases the bony extremities are united in bony ankylosis. Whether the ankylosis is of the fibrous or bony variety, the finger is placed in a position of flexion from the contraction of the stronger set of muscles, unless the surgeon, in the process of treatment, has seen fit to maintain the position in some other more desirable angle by the application of suitable splints.

There are other cases of interphalangeal inflammation in which the symptoms are varied by the involvement of the overlying tendon-sheath. Under these circumstances to the swelling due to the involvement of the soft parts and the joint is added a deeper swelling. This extends in both directions parallel to the tendon sheath, is elongated in shape and owing to its being confined beneath non-yielding connective-tissue, is deeply elastic to the touch.

The position of the extremity is determined by the contraction of the tendon involved and any attempt to antagonize its action elicits most intense pain, resembling a similar symptom in joint involvement, where passive movement can scarcely be endured by the patient. It may be differentiated by the fact that the tendon may be placed on the stretch by the passive movement of a joint that is free from inflammation, while the joint involved is temporarily immobilized; thus, if the metacarpophalangeal joint only is involved, passive movement at that joint causes severe pain; passive movement at either of the distal interphalangeal joints is painless, provided that the metacarpophalangeal joint is fixed. If, however, the flexor sheath is involved, passive movement at either of these normal joints is sure to cause pain because by that movement the inflamed tendon is elongated, while the pain due to the inflamed metacarpophalangeal joint is excluded by temporary fixation of that joint.

The presence of this complication is easily detected by the spreading of the swelling toward the belly of the tendon, even before the pus reaches the surface. With the rupture of the abscess, the diagnosis is rendered certain by the appearance of the sloughy tendon in the abscess cavity.

The subsequent separation of the necrotic por-

tion of the tendon is accompanied by a radical change in the position of the finger. If, for example, the flexor tendon of the index finger has been involved it has been strongly flexed in the early stages of the inflammation, less strongly flexed when the pus reaches the surface, and when separation of the slough takes place, the extensor tendon, without check, hyperextends the finger precisely as if the healthy flexor tendon had been divided in an incised wound. Passive flexion is still allowed in the phalangeal joints, but as soon as the pressure is withdrawn the tip of the finger is pulled back by the contraction of the extensor tendon. This impaired function is permanent as nature does not replace the destroyed tendon. The occurrence of suppuration in the tendon sheaths intensifies the constitutional disturbance accompanying the process of infection, and in cases in which this process is extensive may threaten the life of the patient from toxemia.

Treatment.—The treatment of these cases of finger-joint infection depends on whether the joint alone or the tendon sheath in addition is involved. The principles observed in both cases are indentical. The application of suitable dressings to the part, which is kept elevated and in absolute rest, is reinforced by incisions which allow generous drainage and thereby prevent the retention of any foul material in the area of inflammation.

In the case of joint involvement the incisions should be on either side, made if possible where the joint is most superficial, thoroughly exposing the synovial cavity and the articular ends of the bone, avoiding, naturally, any adjacent normal tendon sheath. In severe cases the drainage of the joint cavity is still further facilitated by the resection of the articular extremities of the bone.

Absolute rest is afforded by the application of a suitable splint which extends above the wrist on the palmar surface. Wet dressings of aluminum acetate or of aqueous solutions of carbolic acid, 1 to 60, or of bichloride of mercury, 1 to 10,000, may be utilized in the early stages of the infection. Recently, in the Vanderbilt Clinic, a ten-per-cent. aqueous solution of ichthyol has been used with advantage. In the severer types the inflamed part may be continuously immersed in a bath containing any one of these solutions, preference being given to the aluminum acetate.

In those cases in which the nature of the infection is such as to cause serious toxemia, the patient must be kept in bed and subjected to the usual constitutional treatment of this condition, the local measures already outlined being carried out as early as possible after the onset of the infection, the necessary incisions for the relief of the tension being most efficacious when they are made through the entire area of infection in length, breadth and depth.

The severest type of finger-joint infection is seen in those virulent cases in which local gangrene of the entire finger develops while the process rapidly extends along the extremity to the elbow and axilla. In these cases amputation is the only remedy and must be done without delay if the life of the patient is to be saved. This measure, by removing *en masse* an area crowded with germ activity and their toxic products, diminishes the virus, which it is necessary for the organism to destroy or eliminate if recovery is to take place. In favorable cases it is followed by the subsidence of both local and constitutional symptoms. While providing proper local treatment in these serious cases of infection, the general septic condition of the patient must receive careful attention, the indications being chiefly to promote the excretory power of the organs of elimination, while the general system must receive the support of generous doses of alcohol and, if necessary, of other stimulants.

In from one to three weeks, according to the degree and extent of the infection, the process of destruction comes to an end and is followed by the stage of repair. The separation of sloughy from viable tissue can best be hastened by the daily irrigation of the abscess cavities with peroxide of hydrogen, followed by the application of gauze soaked in a liquid balsam of Peru. Proper immobilization of the joint should still be maintained in that position in which, if ankylosis takes place, the finger will prove most useful to the patient. This process of repair requires an average interval of two months before healing is complete. If at the end of this rather protracted period complete restoration of the function of the part could be promised, the sacrifice of the finger would never, except in the severer type of cases already mentioned, have been a subject for debate; but, unhappily, in the majority of cases of joint infection a stiff finger results which very greatly impairs its future utility if, indeed, the finger is not actually in the patient's way. With such an unfavorable prognosis, is not the amputation of the part, as soon as the involvement of the joint is a certainty, to be greatly preferred to the conservative plan of treatment? This I maintain is a question for the patient and not for the surgeon to decide, as long as the retention of the finger is without risk. Some patients, including those encountered in the dispensary, prize very highly a finger that is stiff and worthless; other men, belonging to the laboring classes prefer to resume active work as soon as possible, the loss of an extra two months of daily dressing necessitating the incurring of debt and the suffering of hardship. Under these circumstances amputation is always to be advised, if the process involves unimportant fingers.

The advantages of the conservative plan of treatment, which it has been my custom to present to patients applying for treatment of these infections, is that, in the first place, there is a slight chance of their obtaining a movable joint. In other words there is a chance for the complete restoration of function when the joint only is involved; secondly, that if stiffness results the finger may yet prove serviceable, particularly in

the case of the thumb and of the index finger, and that, if they can afford to wait until the part is entirely healed, the finger can then be sacrificed if it proves useless. At least four-fifths of the patients selected this conservative plan of treatment. The finger may prove most useful, even stiff, if the proper angle of ankylosis is established by the surgeon. In one of the cases reported (*Case I.*) the patient, a mason by occupation, found the right index finger very useful in his daily work, although the metacarpophalangeal joint was completely ankylosed as a result of an infection of three months' duration. The angle of ankylosis was established at 135°, which enabled the patient to accurately direct the point of one of his tools.

If the joint infection has been accompanied simultaneously by a similar process in the tendon sheath, restoration of function is, of course, impossible. If the infection of this nature has involved the 3d, 4th, or 5th fingers, amputation is desirable unless the patient desires the preservation of the finger for cosmetic reasons. The importance of the preservation of the index finger or thumb, if involved, demands conservative treatment. If, with the destruction of the tendon, the metacarpophalangeal joint is intact, the patient can be assured of the restoration of function of flexion of the first phalanx, through the action of the lumbricales, inasmuch as the destruction of the tendon rarely occurs beyond the origin of the muscle; when, however the joint, as well as the adjacent tendon sheath, is involved, a stiff finger only can result, the utility of which time alone can demonstrate.

The following cases are selected from a large number and their histories are related with the intention of presenting the different clinical features of joint and tendon infection:

Case I.—J. S.; mason; thirty-five years of age; November, 1893. Two days ago, in an altercation, the patient struck a man in the mouth, receiving a punctured wound over the posterior aspect of the right metacarpophalangeal joint from one of the incisor teeth. From this puncture the patient noticed the escape of a small quantity of viscid, tenacious fluid. Within the next twenty-four hours he suffered an increasing amount of pain, intensified by any attempt to move the finger, the position of which gradually became more and more fixed. At the same time the parts around the wound became red, swollen and tender. He was unable to sleep at night and lost his appetite. He had some fever but did not have a chill. On examination there was considerable swelling in the vicinity of the right metacarpophalangeal joint of the index finger, extending upward along the dorsum of the hand and downward toward the tip of the finger. Over the joint proper there was a small punctured wound of sloughy appearance, from which a small amount of seropurulent fluid issued. The swelling was red and elastic over the situation of the joint, tenderness being elicited around its entire circumference. The finger was in flexion and any attempt to produce extension caused severe pain. There was complete abrogation of function. There was moderate elevation of pulse and temperature.

Under nitrous oxide gas incisions were made over the laterodorsal aspect of the joint, the cavity of which was found to be moderately distended with seropurulent fluid. The cartilaginous extremities were intact and the capsule in a healthy condition. The joint was washed out with an aqueous solution of bichloride of mercury, 1 to 10,000, drained with strips of iodoform gauze, and immobilized by a splint at an angle of 135°. The patient made an uninterrupted recovery, although the process of repair required three months. At the end of that time the sinuses had completely closed without the exfoliation of any bone, leaving a joint the site of fibrous ankylosis, with absolutely no movement. The angle of fixation, however, enabled the patient to satisfactorily use the finger in his daily work.

This case is an example of a frequent mode of infection. A punctured wound, inflicted by a man's tooth allowed the infectious material present on the tooth to enter the wound if not the joint. Such cases are invariably severe, require a long time before healing takes place, and invariably result in ankylosis of the joint.

Case II.—B. C.; twenty-one years old; laborer; March, 1894. Four days ago the patient received a punctured wound from a rusty nail over the dorsal aspect of the second interphalangeal joint of the right middle finger. This was followed by severe pain and loss of function, the patient being unable to move the finger, as well as by the usual symptoms of inflammation around the site of the wound for which the patient sought relief at the Vanderbilt Clinic. Examination showed a small sloughy orifice of a punctured wound, over the dorsal aspect of the above-mentioned joint, discharging pus; around it the swelling was so pronounced that the circumference of the finger was double that of its normal fellow. There was considerable thickening of the terminal phalanx. A probe passed into the cavity of the joint touched smooth, bare bone. There was abnormal lateral mobility of the joint due to the insufficient lateral ligaments, and with this movement smooth crepitus was elicited.

Operation under nitrous oxide. A free incision was made over the laterodorsal aspect of the joint, the cavity of which contained a small amount of purulent fluid. The articular cartilage of the terminal phalanx was markedly denuded, that of the second phalanx smooth and glistening. The tendon sheaths were normal. Irrigation of the joint cavity with a solution of bichloride of mercury, 1 to 10,000, drainage with a strip of iodoform gauze, and immobilization with the customary splint. A wet dressing of aluminum acetate was applied. The operation was followed by the subsidence of the local symptoms and by the speedy establishment of the process of repair. The terminal phalanx became ex-

foliated and was removed at the end of the third week; rapid healing was completed during the fourth week. The splint was then removed and the patient allowed to move the finger at will. The movement was gradually restored and at the end of the second month the patient declared that the function of the finger was as good and as strong as formerly.

This case illustrates an infection of a minor joint in which the entire phalanx became necrosed, and notwithstanding this complete function was restored. This fortunate result was probably due to the fact that the articular cartilage of the second phalanx did not become denuded and, therefore, favored the formation of a new joint. It must be stated, however, that the perfect restoration of function in this way is very unusual; occasionally the surgeon obtains a partial restoration of function.

Case III.—M. C.; twenty-five years old; March, 1897. Ten days ago the patient struck a man in the jaw. This was followed, according to the patient's story, by the appearance of the usual symptoms of inflammation over the dorsal aspect of the right index finger. Poultices were applied and after four days an abscess opened spontaneously, discharging a considerable quantity of pus. Since that time the swelling has persisted, the hand was still useless, and patient sought advice at the Vanderbilt Clinic. Examination showed marked inflammatory swelling over the dorsal aspect of the hand and the radial side of the right index finger. Over the metacarpophalangeal joint of the index finger, there were several sinuses which communicated with the interior of the joint cavity, the probe touching roughened bone. There was abnormal lateral mobility and with this lateral motion a rough, harsh crepitus was elicited. Patient had a moderate increase of temperature and elevation of the pulse.

Operation under cocaine. Incision, three inches in length on the dorsal aspect, exposing the joint and extending upward through the area of exudation. The usual irrigation was practised and the incisions were packed loosely with iodoform gauze. Joint immobilization. On the following day the constitutional symptoms had increased in severity and the local symptoms, not having perceptibly diminished, the patient complained of greater pain, ether was administered and the ends of the roughened articular bones removed, a counteropening was made on the palmar surface of the joint, without disturbing either the extensor or the flexor tendon, and iodoform gauze was introduced through the opening thus made. This operation was followed by a subsidence of both the local and the constitutional symptoms and in the course of the next three weeks the process of repair had become well established. Two months afterward the palmar incision had entirely healed, and there remained only a persisting sinus over the joint that discharged a small amount of pus for two weeks longer. When the parts had entirely healed fibrous ankylosis remained with the joint in a position of slight flexion.

This case is of interest, because it was not subjected to suitable treatment until ten days after the infection had taken place. With this disadvantage, it was still possible to save the finger, although satisfactory drainage was not obtained until the joint was opened anteriorly, the articular ends of the bone removed simultaneously, and the amount of infecting material thus decreased. When the patient resumed work, the finger, although stiff, was sufficiently useful to make its retention desirable.

Case IV.—S. B.; thirty-two years of age; broker. Twelve hours previous to examination, while bathing, a small fragment of glass became imbedded in the palmar surface of the right middle finger, over the junction of the first and second phalanges. This the patient removed with an old razor. Several hours later he developed a chill and a sudden rise of temperature, and simultaneously the finger began to swell and became excruciatingly painful. Examination showed a moderately swollen finger which presented upon both dorsal and palmar aspects numerous inoculating reddened bands, extending up on the dorsum of hand and lower forearm. At the site of the puncture there was a small quantity of pus and about it the swelling was extremely tense and painful. There was complete loss of function, the finger being fixed in flexion. Temperature 104.5° F.; pulse 120.

Operation under local anesthesia by means of ethyl oxide. A crucial incision was made through the area of infection and others at the lateral aspects of the junction of the palm of the hand and the finger. A very small quantity of pus was evacuated at the point of infection. Elsewhere the incisions passed through thickened skin into normal subcutaneous tissue. There was not any evidence of joint or tendon-sheath involvement. The incisions were packed with iodoform gauze and a wet dressing of aluminum acetate was applied, the limb being supported upon a pillow. During the next three days the temperature and pulse continued high and at times there was slight delirium. Locally the swelling increased and showed a tendency to involve the lower part of the palm of the hand, as well as the dorsal region over the vicinity of the metacarpophalangeal joint. Another incision under cocaine was made in this latter situation without, however, finding any pus. The extensor sheath was exposed and found to be normal. On the following day pus issued through the side of this incision coming from an abscess cavity anteriorly, which, opened, was found to embrace the sheath of the flexor tendons. This abscess cavity formed a communication with the original incision at the point of infection. With the exit of the pus, the constitutional symptoms subsided, and the patient's general condition improved. The drainage from the suppurating tendon sheath was at first satisfactory, but at the end of the second week considerable oozing

of blood took place from the wound, an evidence of insufficient drainage, and in order to correct this the two palmar incisions were connected, thus exposing the entire suppurating tendon-sheath cavity. There was still further subsidence of the constitutional symptoms, the temperature and pulse reaching normal at the end of the fourth week. At about the tenth day suppuration appeared in the joint between the first and second phalanges, and the second phalanx itself became extensively swollen and denuded. Drainage was, however, satisfactorily accomplished through the long anterior incision, and no perceptible exfoliation of bone took place. The anterior surface of the corresponding metacarpophalangeal bone also became denuded, but subsequently became covered by granulation tissue. At the end of the sixth week the sloughy tendon sheaths had separated from their viable portions, that of the sublimis being the first to come away. At the end of the tenth week the healing process was complete. The finger was shortened half an inch and the joint between the first and second phalanges was in a condition of fibrous ankylosis in a position of slight flexion.

This case is one of unusual interest. Originally the infection was introduced a short distance only beneath the skin and from this point, notwithstanding early and extensive incisions, the infecting material was carried not only into the tendon sheath, but also into the joint. The separation of necrotic tendon required several weeks longer than usually is the case; in fact, at one time it was hoped that notwithstanding the suppurative tenosynovitis the viability of the tendon might be preserved. The arthritis behaved in a very peculiar way. The second phalanx was double its normal size and denuded through a considerable part of its extent, yet exfoliation did not take place *en masse*, although that there must have been some gradual loss of bone is demonstrated by the permanent shortening of the finger. The thickened condition of the phalanx persisted months after healing was complete. The occurrence of secondary hemorrhage was an indication merely of insufficient drainage of the abscess cavity. This demanded the joining together of the incisions on the anterior aspect of the finger and lower palm of the hand, a procedure which is usually necessary before the abscess cavity will heal.

THE PREVENTION AND TREATMENT OF "COLDS."[1]

By W SCHEPPEGRELL, A.M., M.D.,
OF NEW ORLEANS.

The term "cold" is vaguely and indefinitely used by the masses to designate a morbid affection supposed to be due to the action of cold. It is most frequently applied to an inflammatory process involving the upper air passages and attended by sneezing, congestion and irritation of the nasal mucous membrane, and discharge from the nostrils, with or without soreness of the throat, hoarseness and cough.

That this affection has earned for itself the title of "cold" would lead us to believe that this agent is the most important factor, if not the only one in the development of this condition. It is an accepted fact, however, that the hunter, the soldier in camp-life, and others, who live chiefly out of doors, and are exposed to all the inclemencies and changes of the weather, are rarely affected with colds, whilst those living in houses containing the most modern appliances for preventing the access of cold, and wearing the warmest of woolen clothing, are exceedingly prone to this affection. In fact, it would appear that the higher the point to which these artificial conditions are carried the more disposed the subject is to suffer from its effect.

We must admit, therefore, that whatever effect cold has, it is certainly not the most important factor in the development of coryza. On the contrary, the overheated rooms and the heavy woolen clothing relax the skin and moisten it with perspiration and thus decrease its normal resistance to thermic and hygrometric changes, so that the least draft or change of temperature makes the patient liable to this affection. In addition to this, the lack of ventilation and of ordinary sanitation, added to the predisposing effect of repeated attacks of coryza, tends to disorganize the nasal function of respiration where this is not already affected, and which may form an important etiologic factor in the development of recurrences.

Coryza is of such frequent occurrence and plays so important a rôle in the development of other affections that the subject merits the most careful consideration, especially as the most diverse opinions exist as to its etiology and treatment.

In this affection, as in all others, prophylaxis is of the first importance. Overheated rooms should be avoided, especially those heated by means of steam or hot water, in which the change of air which is incident to the use of the grate, stove or fireplace, does not take place. The clothing should not be too heavy or warm, as this is as liable to cause a coryza as the opposite extreme. I would call special attention to this, as the majority of patients believe themselves to be proof against "taking cold" in the direct ratio of the amount of material they wear. They do not realize that the excess of clothing induces moisture of the skin, and that this, on evaporating, abstracts considerable heat from the body, and also that it interferes with the active functions of the heat centers. It is on this account that wraps, overcoats, etc., should be removed when entering a warm room, otherwise a coryza is easily contracted when the wearer is again exposed to cold or wind.

One of the most useful methods of preventing coryza is the use of the cold shower-bath. The patient should take a warm shower-bath, using

[1] Read before the Louisiana State Medical Society, April, 1900.

soap and rubbing briskly to cleanse and stimulate the skin. This should be followed by a cold shower-bath, the temperature being from 50° F. to 70° F., according to the tolerance of the patient. The systematic and regular use of this method stimulates not only the skin but the whole vascular and nervous system and prepares the subject against the sudden meteorologic changes which are so frequent in our climate. The surface of the body being already accustomed to sudden changes of temperature, easily reacts when these are due to the usual natural causes.

In connection with the subject of prophylaxis I must call attention to the importance of having the nasal passages in a normal condition. We are familiar with the physiologic rôle which these play in the respiratory act. They moisten, warm and cleanse the inhaled air, thus protecting the more delicate structures below them from the irritation which would result were this not the case. We demonstrate the necessity of this when, after a tracheotomy in which the nasal function in respiration is abolished, we are compelled to warm and moisten the air of the room, as otherwise the patient would quickly develop an acute bronchitis with possibly a fatal ending, owing to the fact that the air inspired through the tracheotomy-tube has not been prepared by the nostrils for respiration.

With reference to the constitutional treatment, there is no subject about which there exist so many fallacies. The number of remedies which have been recommended for the cure of coryza are legion, while practically there are but few which have any real therapeutic value. One of the most common is quinine sulphate, which is used not only for its supposed prophylactic action in this affection, but also in all stages of its development. My experience and observation has taught me that this drug has little or no effect in this connection, its supposed value being due to the fact that but few persons are really able to recognize the initial stage of a coryza. If the patient sneezes, has a slight congestion in the nostrils, or feels an irritation in his throat, all of which may be due to some transient local condition or to dust or other impurity in the inspired air, he takes five to ten grains of quinine, and when no cold appears the next day, the drug receives the credit, whereas the probability is that no coryza was impending. I have frequently tested this effect and have been compelled to abandon quinine as a prophylactic agent in coryza.

After the initial stage of the coryza has developed, and after a large dose of quinine is taken, it is true that the drug appears to modify, for a time at least, the usual development of the coryza. We must remember, however, that quinine is an irritant, in fact a toxic agent, otherwise it would have no value in the therapeusis of malarial fevers; when, therefore, a large dose is taken, the system exerts itself to expel a source of irritation greater than the one developed in the upper respiratory organs and in this way it relieves for the time being the congestion and inflammation in the same manner that a vesicant acts as a counterirritant. No sooner, however, has the quinine been eliminated from the system than the coryza again develops, and I have repeatedly seen an attack which ordinarily would have run its course in from four to five days been prolonged to two weeks on account of repeated doses of this medicine.

Leaving out quinine, the drugs most frequently administered in coryza are the various forms and combinations of opium, belladonna and aconite. While each of these modifies in some manner the normal development of a coryza, I believe them to have but little value in this connection and that they are actually injurious in a majority of cases.

My personal experience and observation have convinced me that there are but few constitutional remedies of any value in this condition. A certain number of cases of recurrent coryza are due to a uric-acid diathesis and in these the free administration of lithia is indicated and is sometimes very effective; the liberal use of uniced water being also very beneficial. A brisk saline purgative, if taken within the first twenty-four hours, is one of the most useful remedies and one which may be administered in almost all cases without injury.

As regards the local treatment, here again we have an example of the abuse of drug administration. In recent years there has appeared a greater tendency for proscribing cocaine, either alone or combined with other drugs, in the treatment of coryza. I have already, on several occasions, sounded the danger signal against the promiscuous use of this drug and again take this opportunity to warn against its abuse. When cocaine is applied to the congested nasal mucosa it produces a temporary contraction of the blood-vessels, so that the patient appears to be more comfortable for a time. This is, however, soon followed by a relaxation which occurs in from twenty minutes to one hour after the application, and, unless cocaine is again used, the patient is more uncomfortable than he was before. If, however, it is again applied the reaction is more severe and a chronic dilatation of the vascular tissues of the nostrils results, eventually terminating in an intumescence or a hypertrophy of the nasal mucous membrane which is responsible for many of the catarrhal affections which are so common.

Not only has cocaine an injurious local effect, but the literature on the subject shows that a considerable number of cocaine habitués owe their misfortune to its use in affections of the nose and throat and, in a large majority of instances, by the advice of a physician. Cocaine should rarely be used in this condition and never prescribed. It can effect but little good and has enormous possibilities for evil. The simplest and at the same time the most beneficial treatment consists in bathing the nostrils with a warm

one-half per cent. salt solution. This normal physiologic solution soothes the mucous membrane and washes it free of acrid or tenacious secretions and is absolutely uninjurious to the mucous membrane when properly applied. After its use by means of some form of douche, the atomizer not being so efficient, the patient should not blow the nostrils for ten or twenty minutes, so as to avoid forcing any of the solution into the Eustachian tube. The solution should be used gently and with only sufficient pressure to allow it to pass through the throat and the other nostril. Where ordinary precautions have been used, I have never seen a case where an irritation of the ear has been produced by its use. While this treatment is simply palliative it has the advantage of being free of any ill effects, which cannot be said of other methods of treatment.

The admitted difficulty in the treatment of this very common affection emphasizes all the more the importance of prophylaxis. It also demonstrates that in the treatment of local affections we should not forget the importance of general conditions. When the skin and vascular and nervous systems have been stimulated and strengthened in the manner already described, and the upper respiratory passages have been placed in their normal condition, coryzas are of rare occurrence and, if from some unusual cause they do develop, they are easily controlled.

TREATMENT OF RHEUMATISM AND SOME PHASES OF INDIGESTION; GOUTY DIATHESIS.

By CHARLES E. PAGE, M.D.,
OF BOSTON.

DOUBTLESS it would be a great loss, finally, to scientific medicine to abolish everything savoring of empiricism in medical treatment, whether in or out of the regular profession. It is very generally conceded that the treatment of many disorders is still largely, if not mainly, empirical, and this applies, perhaps, as much to the treatment of rheumatism and gout as to almost any other disease. The late Lawson Tait remarked that the only way an operation could be estimated justly was to ascertain its remote results. "It would matter very little if an operation had no primary mortality at all if it left the majority of its subjects maimed, halt, or insane at the end of two years." The same principle applies to the medical treatment of any disease; the frequent happy effects of the salicylates in banishing pain in rheumatism or gout are well known; but we have to face an occasional fatal result, and it is doubtful if the free use of such medicaments is ever unattended with subsequent ill effects, whether or not the patients or medical attendants are able to trace them to their true cause.

In my practice I have almost wholly discarded the salicylates in rheumatism and gout of late years, and have depended very largely upon hydrotherapy and strict regulation of the diet and general regimen, and have had much better results. From time to time, however, in obstinate cases I have tried one or another of the newer remedies, but as a rule without satisfactory results. Frequently during the past year a friend of mine, a physician of broad experience and a very careful man, has urged upon me his successes with piperazin water, a combination of phenocoll and piperazin, which has given him great satisfaction. Within a few months I have had, along with numerous mild cases, two very ugly cases of rheumatism in which I employed piperazin water and with rather surprisingly good effect.

Case I.—Miss P. G., aged sixty-six years, was for the past ten years unable to move about the house or even rise from or sit down in her chair without the aid of two crutches. Most of the time during these years every movement has been attended with severe and at times excruciating pain in the back, hips, knees and ankles. Her height is five feet and she weighed 223 pounds. Two years ago she had pneumonia and was "very sick a long time." In addition to most of the uncomfortable symptoms of obese subjects, so well known to all practitioners, she was utterly unable to retain her urine. "It runs from me regardless of all efforts to arrest it," she said. In spite of all her troubles her appetite was good and bowels "regular," as she claimed, but in fact she had two or three movements a day. She had tried to curb her appetite and had made some effort to exercise to keep her weight down; but several weeks before consulting me the exercise had caused extreme pain and "flowing," which confined her to bed for a week, when she "was again crawling round on two crutches." Urinalysis showed relation of urea to uric acid to be about 50 to 1. The urine was dribbling constantly, although the total quantity excreted was much below the normal. I put her at once on a very much restricted diet, moderate amount of whole-meal bread and fruit, and had her take one bottle of piperazin water daily, and all the fresh, cold water she cared for, all fluids to be taken on empty stomach. I allowed her two meals a day, breakfast between seven and eight and dinner at night. The first marked improvement was shown in increased flow of urine, and with some degree of capacity for retaining it. Within one week there was no further involuntary discharge of urine, and the pain was less constant and less severe. The relation between urea and uric acid steadily approached the normal, and on the fourth week it was practically normal, the amount of uric acid having increased, a change which must have been due to the drug, since the simple diet could not tend to increase the formation of this product; quite the contrary, in my judgment. I had proscribed the wearing of corsets and directed her to sit very little, but to lie down in nightgown and wrapper

for rest during the day; and I encouraged her to move about moderately and to gradually work up in the amount and vigor of her exercises. It has been my practice of late to discourage sitting in all these chronic cases, having patients rest from the fatigue of moderate exercise by lying down, and to rest from lying down by rising and moving about.

In this case the patient steadily lost weight and as steadily increased in strength. At the end of six months she weighed 160 pounds, having reduced about 63 pounds. She was now practically free from pain; she could rise from her chair with but slight aid from her crutches, and she could move about quite easily. Her bowels moved naturally five or six times a week, and urine was passed naturally four or five times a day. No other medicament but the piperazin water has been used, and of this she has taken the one bottle a day, and is at the present time steadily improving, losing about 2 pounds every week, and gaining in muscular strength and suppleness. Her heart, which was unmistakably fatty and weak, has shared in this increased strength; her complexion has become clear, her eyes bright, and her hearing, which was very deficient, has also improved somewhat. She is now able to do all of her own work about the house, and has actually "cleaned house" within the past week without assistance. She still keeps her crutches by her, and uses them when she goes out-of-doors. I have not encouraged her to abandon their use, believing that they are useful in the way of giving her needed "fore-quarter exercise," as well as in relieving the legs from the still excessive weight while they are gradually gaining in strength.

I am not alone in the belief that rheumatism is "a phase of dyspepsia," to quote the words of Dr. Casey Wood, who first gave me this thought; and from the steady improvement in digestion and assimilation in the above case, and the speedy relief from the pain, I am compelled to believe that the piperazin water has acted as a powerful disinfectant or preventive of the autotoxemia formerly constantly occurring from the absorption of ptomains from the gastrointestinal tract.

With this case in view I have employed the water in several cases of chronic dyspepsia within the past few weeks, and with marked improvement in each instance. In one case of chronic dyspepsia and constipation, in which the patient, male, sixty years of age, with insomnia and a victim of melancholia bordering closely upon insanity, the employment of piperazin water, with little modification of diet, beyond prohibiting the patient from taking a morsel of food except when he was sharply hungry—that is, he was to skip any regular meal and to wait until the next meal-time, whenever his appetite was the least "finicky"—produced results little short of miraculous; the patient, an emaciated dyspeptic, accustomed to force or tempt his appetite, in the idea that much eating would help put on flesh, regardless of indigestion and malassimilation, shortly had a reliable appetite for every meal; his bowels became quite regular, and he would sleep five or six hours soundly every night; his courage and spirits returned and his illusions were banished. I am confident that this was a case of chronic ptomain-poisoning from putrescent food-substances in the intestines, the product of indigestion. This patient is at present gaining in weight, sleeps well, and is improving steadily in strength, from the exercises prescribed and improved digestion. In none of the cases in which I have employed the piperazin water has there been any disturbance of any sort which I could attribute to its use; on the contrary, it has seemed to agree perfectly.

Case II.—Mr. P. C., broker, aged forty-five years, naturally rather a robust man. Within the past ten years he has had two very severe attacks of inflammatory rheumatism. He is a heavy feeder, eats freely of animal food and is a moderate drinker. He has habitually a great deal of trouble with his feet and ankles; wears a gout-boot most of the time, and is unmistakably of the gouty diathesis. He consulted me on April 21, 1900. He was confined to the house with severe pain in hips, knees, ankles and feet. Temperature 102.5° F. No appetite; had had no movement of the bowels for weeks without active purgatives. I directed complete rest in bed, and abstinence from food till indicated by hunger. Prescribed piperazin water, one bottle a day, and he was to take fresh water as freely as he could without inconvenience. The inflamed joints were kept cold-packed—thickly-folded linen towels wrung tightly from ice-water (extra towels kept on ice ready to change as often as the ones in use became at all hot) wound around the joints and well covered. A modicum of the piperazin water was poured over the damp packs. The relief from pain was quite marked, the local inflammation was shortly modified very satisfactorily about all the affected joints. The elbows and wrists had their turn at the process during the three weeks of illness, but in comparatively mild form. The temperature shortly came down to 100° F., and remained about at that point, no effort being made to lower the temperature with medicinal antipyretics. He held to the water-diet without claiming the least inconvenience for the first four days, the tongue gradually cleaning, pain moderate, and he got several hours sleep every day. On the fifth day he thought he could relish a piece of stale graham bread. He did eat a small slice with keen relish and also a couple of oranges later in the day. From that time on he had two moderate meals of fruit and bread, and on May 14th made a visit to his office. He continued the piperazin water in half-bottle portions daily for the next three weeks, and is at present in excellent condition. Compared with his former experiences he called this a very comfortable sickness, although he declares that it started in quite as ugly fashion as either of his former attacks.

For many years past I have regarded it as altogether unphysiological, and in every way bad practice, to feed any fever patient during the progress of the disease. This was the rule with Hippocrates, and in many hundreds of cases I have held to it with satisfaction. "Eating, like every other natural function," says Oswald, "should be a pleasure and not a penance." It is no penance for these patients to abstain from solid food in face of lack of appetite; it is rather a pleasure to be saved from the prevailing practice of forced-feeding. When hunger returns there is pleasure in eating and a promise of digestion and assimilation. The food does good, not harm.

The belief seems to be gaining ground among thoughtful physicians everywhere that autotoxemia is a factor in the causation and continuation of most, if not all, diseases. Numerous cases come to autopsy in which no visible cause for a much-disturbed mental state can be discovered, notwithstanding the most approved technic has been applied. "The investigation at the present time of the toxins formed in the gastrointestinal tract and the rôle autoinfection plays in the production of disturbed mental states," says Dr. S. C. Fuller in a recent essay, "has already thrown a flood of light on the etiology of epilepsy, some forms of melancholia, mania, and other nervous conditions not essentially mental." It does not follow, of course, that all intoxications necessarily proceed from the gastrointestinal tract, nor that autointoxication is the sole cause of all mental and physical infirmities; but in view of the prevailing living-habits of human beings, distinctively artificial and unwholesome as we know them to be, notably in case of sedentary persons who indulge freely in animal food two or three times a day, is it not altogether rational to assume that we have to reckon with malnutrition in considering the etiology and treatment of most diseases, whether chronic or acute? Dr. McCaskey recently suggested that "rheumatoid arthritis is a toxemia from the gastrointestinal tract." I can imagine no more natural or prolific source of uric-acid formation than the constant presence in the alimentary tract of putrescent food-substances from bad and overeating; and I attribute my unusual success in the treatment of both acute and chronic rheumatism to the active solvent properties of the piperazin water employed and to the rigid diet imposed.

Remarking that "the vegetarian and fruitarian are not urid-acid subjects, except under certain abnormal conditions when they may become meat eaters by subsisting upon their own tissues," Dr. H. A. Rundlett says: "There is, and that is within the knowledge and experience of all medical men, no single person who eats meat constantly that does not exhibit in some form symptoms due to insufficient excretion of uric acid or uric-acid poisoning, for that is what they indicate. Dull headaches, subacute muscular pains, tender fibrous tissues everywhere, reluctant and painful joints, heavy and unrefreshing sleep, mental hebetude, irregular and weak heart, inflammations of the mucous membranes or affections of the throat and nose, Riggs' disease of the gums, nervous irritability, and the rest of the tale, all appear in persons sound organically and wholly without any apparent reason for their complainings. These subjects will be found almost invariably to be hearty consumers of meat twice or thrice daily. Their urine carefully examined will show a higher percentage of urea as compared with uric acid, and the ordinary proportion of 35 to 1 may be found to be 50 to 1 or as low as 80 to 1."

The chief problem, then, in all these cases is to diminish the formation and increase the elimination of uric acid; and hence the value of a potent and at the same time non-toxic solvent of uric acid such as the piperazin water has proved to be in the cases cited.

MEDICAL PROGRESS.

Silver Wire in Surgery.—A. M. Phelps (*Med. Rec.*, September 22, 1900) states that in addition to using silver wire for suturing the tissues in hernia operations, we may use it in large cranial wounds with much loss of bony structure, also in restoration of ruptured and lacerated muscles; the opening in the skull is closed by stitching across it fine silver wire, including the aponeurosis and periosteum on the other side of the wound; the stitching in the second row is at right angles to the first across the wound; this forms a network which prevents the cicatricial tissue from contracting and making pressure upon the brain; it also prevents hernia cerebri. In rupture of muscles or in loss of muscular tissue from injury, the muscles may be stitched together with a continued suture and when there is loss of muscular substance the wire should be stretched across from end to end of the muscle, care being taken that the wire be in the center of the muscle with no ends projecting when reproduction has taken place; such muscles are as strong after reproduction as before the injury and the scar tissue between the ends of the ruptured muscles, for instance, the quadriceps extensor femoris or the biceps flexor cubiti will not stretch because the encysted wire will prevent it. The presence of the silver wire will never occasion disturbance and suppuration is not produced by the wire unless the germs of infection are introduced with it.

Membranous Enteritis.—Membranous enteritis is a rare disease, characterized by irregular paroxysms of abdominal pain, tenderness, tenesmus, and the passage of shreds, tubes and membranes of mucus, occasionally forming exact casts of the bowel. Up to 1888 only 116 cases had been reported, of which only 8 were fatal. H. L. Slifer (*N. Y. Med. Jour.*, September 22, 1900) adds three cases which are characteristic of the con-

dition. It is most common between the ages of thirty and forty and about eighty per cent. are among women, especially those of a neurotic type. The characteristic symptoms are derangements of the digestive organs varying much in degree, with vomiting and diarrhea or obstinate constipation. Intestinal colic usually precedes the evacuations and disappears after purgation. It may be localized in the left side along the course of the colon. Palpation is painful. The membrane is thin, smooth, and soft, of a yellow color. It presents the appearance of a structureless, transparent jelly-like membrane similar to the white of an egg. Chemically it consists of mucin and an albuminous substance. Microscopically, the exudate is made up of opaque white matter, in which are imbedded epithelial cells, crystals, bacteria and particles of food. Da Costa believes it to be due to "the nerves presiding over nutrition and secretion." W. H. Thomson thinks that direct mechanical irritation of the rectum, as horseback or bicycle riding, or pressure from uterine fibroids upon the rectum, or habitual constipation, gives rise to it. The treatment must be directed to the relief of pain and removal of the membrane, and also to the removal of the cause. Opiates may be necessary during the acute stage. High enemata of water or oil usually give relief. The author believes that a course of iron, arsenic and strychnine is beneficial. Small and frequent doses of castor oil are soothing and effectual in preventing constipation.

Diagnosis of Typhoid.—Though typhoid fever is a disease manifesting itself by various typical symptoms, one must be prepared to meet cases in which one or more of these are absent. Thus A. Berliner and M. Cohn (*Münch. med. Woch.*, September 11, 1900) have found among 45 cases a palpable splenic tumor absent in 6, the roseola in 7. Perfectly normal stools were present in an equal number of cases and constipation occurred in 11. The diazo-reaction has been found to be fairly constant, except in such cases admitted after the third week. In the earlier days of observation many cases other than typhoid had been reported with a positive Widal reaction, but with increased skill and greater care in proper dilution such instances have become less frequent. The authors prefer a dilution of 1 to 30 made with a twelve-hour culture. Attention is drawn to the fact that with older cultures the dead bacilli may cause a precipitation which may be erroneously looked upon as agglutination. Of the total number only one single case has been noted with a negative reaction and the observation that a complicating pneumonia may interfere with a positive result could not be corroborated, although in several cases a mixed infection was present. From a prognostic point of view the Widal test is of less value than from the diagnostic, since in the fatal cases it had persisted until the end. The complications observed were inflammations of the air-passages, hemorrhages from the intestines and kidney, nephritis, superficial abscesses, and in one case, marked by persisting somnolency, an extensive meningeal edema.

Demonstration of the Capsule of Bacteria.—It has been hitherto impossible by the usual methods to prove the presence of a surrounding envelope in those bacteria which are known to possess one, when instead of directly examining the specimen one first prepares a gelatin or agar culture. Icilio Boni (*Münch. med. Woch.*, September 11, 1900) finds that by diluting a loopful of culture with a solution composed of albumin, glycerin and formalin, on a glass slide, then spreading to a very thin film, carefully drying by passing through a flame until no more white fumes are given off and, finally, staining with undiluted Ziehl's solution for one-half minute, a capsule can usually be demonstrated. As a suggestion the author states that this method may be available to prove the presence of a capsule in many other bacteria and thus may be an aid in differential diagnosis as, for instance, between the typhoid and colon bacillus.

Decolorizing Properties of Living Cells.—M. Neisser and F. Wechsberg (*Münch. med. Woch.*, September 11, 1900) have found that the behavior of leucocytes to the aniline dyes is a direct index of their vitality, for if to a fresh exudate there is added a dilute solution of methylene blue, a decolorization takes place which is not seen if the cells are first killed by the addition of quinine or other leucocidal substances. The same has been found to be the case with spermatozoa, ciliated epithelium, bacteria and cells not possessed of motility. This simple procedure will prove of great value in estimating the bactericidal powers of specific blood sera and the bacterial contamination of milk and other food stuffs.

Cinnamic Acid in Tuberculosis.—C. Kraemer (*Therap. Monatshft.*, September, 1900) reviews 186 published cases of tuberculosis treated by intravenous or subcutaneous injections of sodium cinnamate and pronounces a favorable verdict as to its action. All authors are unanimous in considering the drug harmless, although mention is made here and there of slight nervous and vasomotor disturbances and of hemoptyses directly traceable to the injections. The action of cinnamic acid is explained by three factors: (1) An increase of leucocytes in the blood; (2) a walling-in of the tubercles by these leucocytes, and (3) a fibrous transformation or encapsulation. The leucocytosis will increase the alkalinity of the blood and this will permit the peripherally-situated parts of the tubercle to enter into solution, following which the tubercle manifests an increased chemotactic action with resulting zone of round cells which, owing to the increased vascularity, readily undergoes the fibrosis which constitutes the final and most effective step in the cure. Of all the methods of administration, the intravenous is best, since here the leucocytosis is

most marked and the digestion is least liable to suffer.

Citrophen.—Among the many remedies which flood the market, citrophen, according to F. Kornfeld (*Therap. Monatshft.*, September, 1900), deserves more than passing notice. Marked advantages are ready solubility in carbonated waters, a pleasant acidulous taste, and absence of after-effects even in cases of cardiac insufficiency or degeneration of the heart muscles. Not only does it reduce temperature in fevers, but in rheumatic affections and in the various neuroses it often acts as a specific, and in pertussis and chronic morphine-poisoning it is without peer. It has also been recently recommended in influenza and the author can heartily endorse its usefulness.

A New Hernia Operation.—A. M. Phelps (*Med. Rec.*, September 22, 1900) describes a method of his own invention which he believes to be novel, certain, and lasting in its results, being fraught with no dangers and giving in his experience of over 216 cases (46 of which were relapsed Bassini operations, and 51 of which were relapsed McBurney and other operations) perfect results in the radical cure of hernia. Acting on the well-known clinical fact that scar tissue will stretch, whether the wound unites by primary union or not, thus giving a recurrence of hernia after hernia operations, Phelps introduces a continued suture of fine silver wire which becomes encysted and remains so during life, causing no disturbance whatsoever. As retraction of the peritoneum and transversalis fascia is apt to take place after ligation of the sac, he obviates this accident by cutting off the sac, retracting it precisely as in any other abdominal operation, and by stitching up the peritoneum and transversalis fascia with a continued suture of silver wire; over the transversalis fascia and peritoneum a mattress of fine silver wire is placed and the deep layer of muscles stitched over it with continued suture of silver wire. A small glass drainage-tube is inserted down to the wire mattress for the purpose of drainage; if a large hernial opening is to be stopped and there is much attenuation of the muscular coats of the abdominal walls, a second mattress of wire is placed between the layers of muscles and a superficial layer of muscles, together with the aponeurosis stitched over it; the cord is brought out from the inguinal canal externally and inferior to the internal abdominal ring; a notch made by cutting with scissors in the aponeurosis of the muscles prevents strangulation, and the cord lies directly under the skin in its course to the scrotum. The use of catgut, silkwormgut, kangaroo-tendon or silk suture would defeat the very object aimed at, as they are all absorbable, except the latter, which is so liable to cause infection; the silver wire must be taken from a solution of pure carbolic acid and then heated to a red heat in an alcohol-lamp flame, before being introduced into the wound, so as to render it sterile. Should infection take place in the mattress of wire, lay the wound open with a fine curette, scrape out all of the infected portion, and fill the wound with pure carbolic acid; immediately afterward wash it out with alcohol, which is a perfect antidote to the corrosive effects of carbolic acid, and allow the wound to heal by granulation; in the cases so treated not a single one has relapsed.

"Rheumatic and Gouty Diatheses."—For many years it was generally understood that rheumatism was due to the deficient oxidation of carbohydrates and the accumulation of lactic acid in the blood, while gout resulted from incomplete oxidation of proteid material and the presence of uric acid in the tissues. These theories have now, however, been proven improbable by extended investigations, so that the most plausible explanation offered to account for these conditions, and the one which is commonly accepted, is that both maladies result from a suboxidation of proteid food, the pathological and clinical differences being due to the varying influences which digestive disturbances and systemic metabolism have upon the imperfect oxidation of proteid elements. W. H. Porter (*Med. Rec.*, September 22, 1900) believes that the chief cause for such a suboxidation state is the ingestion of more oxidizable food than can be completely reduced to the end-products, but a diminution in food supply, especially when of a poor quality, may so deteriorate the nutritive activity of the system that even the small amount of food taken cannot be properly transformed. Sugars, fats and starches are easily and quickly oxidized, so that large quantities of such food may overtax the oxygenating power of the system, and thus prove to be potent factors in causing the imperfect oxidation of the more difficultly transformed proteid materials. Thus may be explained the peculiar phenomenon that rheumatism is more likely to occur than gout when a carbohydrate diet is used, for it is easy to understand that a suboxidation due to this cause might reasonably be of a different nature than that due to an inordinate quantity of proteid food. Uric acid, although an end-product, is a substance less completely oxidized than urea and hence appears in the urine in larger quantities when the systemic powers of oxidation are deficient. It probably never exists in the blood, is normally formed by the renal cells, but under pathological conditions can be made at abnormal points by the vicarious actions of protoplasmic masses. The author believes that the varying degrees and kinds of suboxidation met with, such as the so-called gouty and rheumatic states, are the result of some special micro-organism acting in the alimentary canal, or may be the result of two or more varieties acting together, or may perhaps be due to the absence of certain kinds of bacterial life which are essential to the normal digestive processes. The two great predisposing factors, then, are the ingestion of too large quantities of nutritive pabulum for perfect oxidation and the ac-

tion of the bacteria on the proteids in the alimentary tract resulting in the formation of toxic materials which are absorbed with the food products. In regard to rheumatic and gouty affections having a direct relation to traumatic and gonorrheal joint-lesions, it is probable that the tendency toward suboxidation already exists in the system and these added pathological changes in the joints merely determine the site for the deficient metabolic processes to manifest themselves. Furthermore it is urged that when we come to cases of acute articular rheumatism we reach a point in which the errors in diet, the action of bacteria in the alimentary canal and the absorption of the toxic products act when they are introduced into the system as the direct etiological factors in determining the special type of suboxidation.

Tuberculous Peritonitis.—A. Kennedy and E. Steele (*Lancet*, August 25, 1900) narrate the history of a boy four and one-half years old, with a family history of tuberculosis, who two weeks prior to admission to the hospital had diarrhea, pain in abdomen, aching in the legs, and loss of flesh and strength; examination revealed an abdomen distended, with stomach-walls tense, yet neither rigid nor tender, with a few ill-defined lumpy swellings about umbilicus, appreciable on palpation. As the symptoms were daily increasing in severity a laparotomy was performed, the intestines being found matted together. The condition of the boy under an anesthesia was so bad that the abdomen was closed forthwith. After a few weeks the boy's general condition had greatly improved; two months later he was discharged from the hospital, cured. The value of a simple laparotomy in tuberculous peritonitis is now acknowledged, the explanation usually given is that opening of the abdominal cavity disturbs the previously existing conditions of exudation and absorption so that the tubercle bacilli are no longer capable of living; although this explanation is not satisfactory, the evidence we possess in regard to the advantages of laparotomy is sufficient to justify the performance of the operation. Drainage seems to be unnecessary and undoubtedly it adds largely to the risk of the operation; flushing with normal salt solution has appeared to be useful, but not essential; the mere making of a small opening into the abdominal cavity, as in the performance of a radical cure of hernia, is not sufficient to have any beneficial effect on the tubercle bacilli.

The Influence of Oophorectomy in Osteomalacia.—E. O. Croft (*Lancet*, August 25, 1900) records the case of a married woman, aged thirty-five, whose previous history as to family, menstruation and other functions was perfectly normal until the sixth month of her first and only pregnancy (which occurred in her thirty-third year), when she began to complain of pain in her back and thighs and difficulty in locomotion; these symptoms continued until the birth of her child, accomplished by instrumental delivery; one week after this event there was a sudden permanent cessation of milk in the breasts. After labor her pains were still present, although walking was more easily accomplished. One year later the pain had extended until it involved the spinal column, ribs, sacrum and pelvis, but the long bones were not involved; all of these symptoms continued unabated until a few months ago, when, because of an absolute inability to walk and the presence of intense pain, she sought hospital treatment. On admission there her abdomen was found to be prominent and pendulous; the symphysis pubis was prominent and the bony outlet of the pelvis markedly contracted; her urine contained no albumin or casts but about twenty-nine grains of phosphoric acid in the forty ounces of urine passed daily. Acting on the theory of Curato and Tarulli, that the internal secretions of the ovaries have the power of oxidizing compounds of phosphorus, such as those which exist in long bones, and that the removal of the ovaries would check the amount of oxidation taking place, thereby increasing the deposit of calcium and magnesium phosphate in the bones, a double oophorectomy was performed on the patient, who made an uninterrupted recovery surgically. Four weeks after operation a marked improvement of the symptoms previously existing was noticed; the pains and stiffness in the back were less annoying and the patient was able to get about with less difficulty, although standing unsupported was both difficult and painful. Too short a time has elapsed since operation to give any more extended observations as to the patient's improvement other than to note a diminution of twenty grains in the amount of phosphoric acid contained in the urine. The internal administration of phosphorus and bone-marrow is said to produce great improvement in cases of osteomalacia.

Urethritis.—Many specifics for this disease have been placed on the market. Of late years the preparations containing silver and mercury have enjoyed a deserved popularity. R. Guiteras (*Lancet*, September 22, 1900) reports on the use of a new one, Mercurol. This is a combination of nucleinic acid and mercury. The nucleinic acid being derived from the albumin compounds of yeast. Its special claims are its lack of irritable properties and its solubility. In the treatment of 150 cases, beginning with one-quarter of one per cent. solutions, gradually increasing to 5 per cent., he has secured results which he believes are better than those obtained by the older methods of balsamic and astringent medication. The stronger solutions were later modified, the final results showed that a two per cent. solution was most efficient. In 100 patients treated with this strength solution, 22 were practically cured in three weeks; 28 in four weeks; 17 cases extended over four weeks; 18 patients ceased to come after two visits and 15 were under treatment. Two patients suffered from complications, Solutions are preferably used fresh. The injections are to be made slowly.

THERAPEUTIC HINTS.

Bromipin in Epilepsy.—*M. Kothe* keeps his patients in bed for several weeks, giving a tepid bath of short duration twice a week. At the same time he gives bromipin, 5 grams (75 grains), t. i. d., by mouth, or 15 grams (225 grains) at bedtime by rectum. In the course of six or seven weeks the dose is increased up to 40 grams (600 grains) a day, is maintained at this for three weeks, then gradually reduced for six or seven weeks.—*Bull. de Méd. de Paris*, Apr., 1900.

Scabies.—At the 1900 meeting of the American Dermatological Association, *S. Sherwell* recommended that, after thorough bathing, the body and limbs be rubbed lightly with washed sulphur, less than half a teaspoonful for each person; this to be followed by clean underclothes and clean sheets with half a dram of sulphur dusted between them. If this is repeated every second or third day the cure, in ordinary cases, is complete in a week. In a large experience the author has seen no resultant dermatitis or failure of cure. The method is clean and free from grease or unpleasant odor, so may be used in logging-camps, ships, etc. T. C. Gilchrist allays the itch by rubbing in balsam of Peru with a soft toothbrush. J. C. White obtains prompt alleviation of the itch and frequently cure in three days by balsam of Peru with or without sulphur or naphtalin. C. W. Allen thinks the balsam too painful to apply to the scratched skin of a child. Geo. T. Elliot has tried styrax and sulphur, but finds the dermatitis produced by the latter to be worse than the itch.

Fetid Rhinitis.—To keep the parts clean and disinfected, Geo. M. Lefferts advises the daily use of the anterior or posterior nasal syringe, the occasional removal, if necessary, of hard crusts by forceps, and washing with an alkaline and antiseptic solution until all offending secretions are removed. Suitable formulæ for this purpose are:

℞	Sodii borat.....	4.0	(3i)
	Glycerit. acidi carbol.....	6.0	(3iss)
	Aquæ	500.0	(Oi)
or			
℞	Ac. salicylici.....	0.6	(gr. x)
	Sodii bicarb.....	4.0	(3i)
	Aquæ	500.	(Oi)
or			
℞	Sodii borat.....	4.0	(3i)
	One per cent. solut. potass. permangan.....	6.0	(3iss)
	Aquæ	500.0	(Oi)

The uncomfortable dryness of the mucous membrane may be in part overcome by the frequent use by the patient of a spray of liquid vaseline.

Acute Gonorrheal Vulvitis.—George M. Tuttle's treatment is rest in bed, light diet, keeping bowels open and urine bland by salines, especially potassium salts, and bathing every three or four hours, using plenty of water rather than antiseptics. Weak carbolic, bichloride, lysol, or boric-acid washes may, however, be of use. After the douche, paint the parts with a two-per-cent. solution of silver nitrate increased rapidly to 10 per cent., and keep the parts separated with gauze wet with lead-and-opium wash to relieve the pain, or weak bichloride, or

℞	Ammon. chlorid.....	4.0	(3i)
	Alcohol	4.0	(3i)
	Witch hazel.....	500.0	(Oi)

If an ointment is preferred use iodoform, 2 to 4 per cent., or bismuth subnitrate and glycerin.

Lobar Pneumonia.—In the cases with no special indication for treatment, says *Francis Delafield*, the patient gets well with rest in bed, careful nursing, and the inhalation of oxygen. Headache, pain, restlessness, and sleeplessness may be relieved by tincture of aconite, 2 drops every hour or two, acetanilid in 3-grain (0.18) doses, deodorized tincture of opium, or the bromides. Large poultices, or

℞	Morph. sulph..	0.003	(gr. 1/20)
	Caffeinæ citrat.	0.06 to 0.25	(gr. i-iv)
	Acetanilid	0.18 to 0.3	(gr. iij-v)

every 3 or 4 hours, do much to promote comfort. If bronchitis is excessive, dry cup the chest, and to diminish the mucus and serum and stimulate the heart give

℞	Fl. ext. digital.....0.06		(♏ i)
	Fl. ext. convallar.....		
	Tr. nucis vom.....aa.	0.3 to 0.6	(♏ v-x)
	Syr. pruni virg.....		
	Aq.. .....aa.	4.0	(3 i)

For the heart's action alone, use whiskey, caffeine, strophanthus, or

℞	Potass. iodid.....0.3		(gr. v)
	Fl. ext. digital.....0.06		(♏ i)
	Fl. ext. convallar.....1.2		(♏ xx)

When there is unusually rapid breathing and rapid heart without much consolidation, give whiskey, 4.0 to 30.0 (3i-3i) e. 3 h. and

℞	Aconitine ...	1/6 mg.	(1/100 grains)
	Digitaline ...	1/8 mg.	(1/120 grains)

every half hour, watching patient closely. When the pulse is reduced to between 90 and 100 per minute, keep it there; if it does not respond in twenty-four hours, stop. In bad cases with rattle of mucus, frequent cupping, large doses of nux vomica, and nitroglycerin, .0012 (gr. 1/50), are indicated. In the few cases where tympanites becomes serious, irrigation of the colon with hot water may relieve. In the protracted cases, resolution may be promoted by having the patient sit up.

Cure of an Attack of Hiccoughing.—*Noir* reports an immediate cure by means of continuous traction on the tongue for one and a half minutes. The patient, a nervous child, had been hiccoughing almost uninterruptedly for six hours; she had failed to respond to the various remedies applied, and was greatly exhausted. There was no recurrence.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

MEDULLARY COCAINIZATION.

When one considers the many directions in which the field of surgery has recently been amplified and its scope extended to embrace formerly unthought-of regions of operative endeavor, while at the same time almost revolutionary innovations in technic have advanced the science in nearly every one of its ramifications, it seems strange that so little has been done to improve our methods of producing general anesthesia, and that the three agents in general use for this purpose to-day are still those employed by a former generation and have come down to us practically unchanged from the middle of the century. Nor is it surprising, when a new procedure is suggested and the possibility of its ultimate development into a measure available for every-day use becomes manifest, that the general interest should be excited to an unusual degree and enthusiastic advocates be found ready to laud its advantages with a somewhat premature fervency of expression.

It is interesting to note that the conception, development and exploitation of the idea of cocainization of the spinal cord have been due to men of three different nationalities, Corning of this city, Bier of Kiel and Tuffier of Paris. In 1885 the first of these, in a work entitled "Local Anesthesia" and in a number of subsequent shorter papers, suggested the possibility of extending the local action of cocaine to a larger area by injecting it into the tissues in the immediate vicinity of the spinal canal with the idea that, owing to the rich vascular supply of the region, the solution would rapidly reach the cord. Although his studies did not lead to any practical result and the method as described is impracticable, the credit of having been the first to conceive of such a possibility undoubtedly belongs to our countryman. Quincke's operation of lumbar puncture, devised purely as a diagnostic aid, should have given the hint, but, although Jacob (*Berlin. klin. Woch.*, 1898, No. 21-22) and Sicard (*Soc. de Biolog.*, 1898, April 30) injected small quantities of inorganic drugs and v. Leyden (*Berlin. klin. Woch.*, 1899, p. 632) administered tetanus serum by this route, it remained for the genius of Bier (*Deutsche Zeitschr. f. Chirurg.*, Vol. LI., p. 361) to combine the observations of his predecessors and bring the method to a practical working basis as we have it to-day. Notwithstanding the interest of Bier's article and the favorable editorial comment it received in this (Medical News, July 1, 1899) and other journals as well as in a communication by Seldowitsch (*Centralblatt. f. Chirurg.*, 1899, No. 41), giving reports of successful cases, his work did not receive a great measure of consideration and it was Tuffier (*Semaine médicale*, 1900, No. 21) who, at the Paris Medical Congress, with the theatrical instincts of his race, exhibited and exploited the method with a dash and *aplomb* that compelled attention and in the eyes of the many crowned him with factitious laurels as its deviser. Since then many operators have published gratifying results, Kreis (*Centralblatt f. Gynäk.*, 1900, No. 28), Severeneau, Racoviceanu, Pitesia, and Nicolette (*Semaine médicale*, 1900, No. 33), and, in this country, S. Marx (Medical News, August 25, 1900, and *Med. Record*, October 6, 1900), J. B. Murphy (*Jour. Amer. Med. Assoc.*, September 1, 1900, and *Chicago Clinic*, September, 1900), J. Riddle Goffe (see p. 559 of this issue), W. W. Keen, F. Kammerer, and others.

The anesthesia produced begins from five to fifteen minutes after the injection and continues for a period of from one to four hours. There is complete loss of pain sense over an area varying somewhat in different individuals independently of the dose employed, but usually extending as far up as the nipple line. There is but little loss

of motor control and the operative manipulations are felt as somewhat unusual sensations, but operations of the greatest severity, laparotomies, amputations, osteoplastic resections, etc., may and have been performed without causing discomfort other than that due to apprehension and nervousness.

At the first blush it might seem that the *ultima thule* of elegant operating had nearly been reached and that a Utopian era was to dawn for the surgeon; the services of the anesthetizing assistant to be dispensed with, the not inconsiderable items of ether and chloroform dropped from the monthly bills of hospitals, cardiac and nephritic cases no longer to be approached with uneasiness, no more inhalation or aspiration pneumonias, and, finally, the pleasure and comfort of operating on a patient cognizant of the operator's wishes and able by voluntary assistance to facilitate many otherwise difficult maneuvers. Indeed, a vivid imagination might conceive of the analogues of the engravings of the old Vesalian and Albinian anatomies, in which delicate ladies daintily hold up the lace work of their own omenta for the inspection of the beholder, in the possible illustrations of the surgeries of the future which might portray the interested patient as assisting the surgeon by holding a retractor or clamping his own arteries.

It is unfortunately true, however, that notwithstanding its great promise for the future, in its present stage the operation does not justify any such rose-colored view, and in spite of the ardent claims of its promulgators we must admit that we are still as far from the *desideratum* of an absolutely safe, universally applicable, general anesthetic as ever. The immediate sequelæ of the operation, nausea, headache, vertigo and general prostration, are always more severe and of longer duration than those usually following chloroform or ether, and, though it seems that these are in most cases amenable to suitable medication, instances are recorded in which they persisted for as long as eight days, and others in which fever, chills and collapse were followed by death. It has not yet been determined whether these symptoms are due to derangements of the intracranial and intraspinal equilibrium following the escape of cerebrospinal fluid, or whether they are to be ascribed to the toxic effects of the drug itself. Lewandovsky (*Zeitschrift f. klin. Med.*, Vol. XL., No. 5-6, 1900), in an exhaustive article on the cerebrospinal fluid, has shown that substances thrown into the subarachnoidean space are directly brought into contact with the nervous elements of the cord through the lymph-spaces without the intervention of the circulation, and our knowledge of the physiology of the nerve-cell is yet too inadequate to justify us in believing that such potent alkaloids are to be directly applied to it with impunity. The comparative frequency with which individuals are encountered whose idiosyncrasy is such that even the ordinary subcutaneous use of cocaine is fraught with serious danger should make one hesitate before indiscriminately using it under conditions which immeasurably increase the risk. Then, again, the operation itself is not at all the harmless procedure it might seem. Gumprecht (*Deutsche med. Woch.*, June 14, 1900) has reported 15 cases of sudden death following lumbar puncture performed simply for diagnostic purposes, and the danger of infection and consequent meningitis is an ever-present and serious menace.

Taking these facts into consideration, however optimistically inclined we may be, we cannot but agree with Bier, who in a recent article (*Münch. med. Woch.*, September 4, 1900), written after over a year's experience with the method, deplores the tendency of over-hasty zealots to accept it as already perfected and ready for universal application, and particularly warns against the large doses that have been used; given a drug of good quality it is never necessary to exceed fifteen milligrams in amount. It should be our object not to continue its use in the already sufficiently exploited and evidently unsatisfactory way as first described, but rather, taking this as a starting-point, to elaborate further measures which shall not be open to the same objections. Means must be sought by which it shall be possible to make the lumbar injection of cocaine as harmless as when practised elsewhere, to abolish the after-effects, and to extend its action so that we shall be enabled to operate on the entire trunk and also the upper extremities. And, most important of all, the effort should be made to effect the anesthesia through the use of non-toxic agents, which has already been successfully done in the case of animals. The difficulties presented by these problems are great, but they are probably not insurmountable and we are justified in entertaining the hope that they will ultimately be overcome. For the present, however, we must be content to regard medullary narcosis not as an accepted fact, but as something still in its chrysalis stage.

MEDICAL ETHICS.

A very good discussion of the ethical relations of the physician to his patients and his fellow practitioners has just appeared in the *International Journal of Ethics,* for October, from the pen of Dr. E. Brudenell Carter of London.

From a fragmentary reading of it the New York *Sun* has assumed that medical ethics are painfully on the wane; and without even hinting at the interest of the article from its revelation of a physician's temptations and his self-denials, launches this bit of pessimism by quoting the following sentence without its context and without a word of explanatory comment: "The tendency in some quarters has been from the standards of a gentleman to the standards of a trades-union; from the standards of a man of honor to the standards of a man of business; from the standards of a philanthropist to the standards of a self-seeker."

The author gives just accounts of the various conditions of modern industrial and social life that encourage the dishonest physician and that tempt the poor and striving man into easier methods of gaining a livelihood. The patients of certain French physicians, as well as those of certain classes the world over, undoubtedly demand that their physician shall assist them to avoid the responsibilities of maternity; the ignorance and superstition of poor working people lead them to patronize by preference the cheap fakir who advertises his medicine and gives his advice free; the vanity of the rich snob who advertises his physician along with his own society notices; and the ambition for wealth and social recognition leads some physicians to push themselves at the risk of their dignity.

All these facts are as true as that human nature is frail, but that physicians are, as a class, degenerating into mere tradesmen, competing with one another in petty ways at the expense of their profession, is not true. There never was a day when an underhand or sordid spirit in a practising physician was more despised, nor were there ever so many honest, skilful, unselfish men, ready to give so much science to disease and comfort to pain for their fee.

The question of medical etiquette is not that of ethics and many of the questions that are discussed as ethics belong in reality to etiquette, which is but the prevailing custom of certain localities and has nothing to do with a physician's integrity and honor.

The code of medical ethics, such, for instance, as is framed by the Manchester Medico-Ethical Society, gives a fair idea of the high standard of propriety and honor in the profession. All self-seeking, all advertising, all secret sharing of profits, all dishonorable attempts to win another man's practice are deemed significant of untrustworthiness; and the expression of such lack of trust by his fellow physicians is considered sufficient disgrace to a right-minded man. If such lack of esteem does not affect a man as much as the lack of cash; and if he confines himself, as must be the case, to a class of patients who have no particular regard for trustworthiness in their physician, they and he may jog along together to their mutual satisfaction; but he does not represent the ethics of the average physician who in the great majority of cases gives more time and service and skill to his patients than is ever paid for, and who makes more sacrifices in a week without counting the cost, than would stock a business man in self-esteem for a year.

No, we admit that, although there are more ways than ever before for the medical profession to go into trade, as it were, we hold that the physician's sense of honor is as keen and his ethical standard as high as ever.

Dr. Carter concludes this article of which the *Sun* quotes the one unhopeful sentence with Robert Louis Stevenson's description of the English doctor. "There are men, and classes of men, that stand above the common herd, the soldier, the sailor, and the shepherd not infrequently, the artist rarely; rarer still the clergyman; the physician almost as a rule. He is the flower (such as it is) of our civilization; and when that stage of man is done with, and only remembered to be marveled at in history, he will be thought to have shared as little as any in the defects of the period, and most notably exhibited the virtues of the race. Generosity he has, such as is possible to those who practise an art, never to those who drive a trade; discretion, tested by a thousand embarrassments; and, what are more important, Heraclean cheerfulness and courage. So it is that he brings an air of cheer into the sick-room, and often enough, though not so often as he wishes, brings healing."

Yellow Fever Patient from Cuba.—E. Bertweer, a saloon passenger aboard the Ward liner *Havana,* which came in on Tuesday from Havana, is ill of yellow fever in Swinburne Island. He is the first yellow fever patient discovered this year in the saloon of any liner plying between New York and Cuba.

ECHOES AND NEWS.

NEW YORK.

Another Death from Jimson Weed.—This is the time of year when Datura Stramonium ripens and the thorn-apple seeds eaten. The daily press announces the death of a six-year-old boy who ate the interior of one thorn apple.

Dismissal of City Hospital Internes.—Two internes on the Blackwell's Island staff were dismissed last week for entertaining young women in their apartments after the lights were out. Superintendent Roberts thought that successors who would be more circumspect were desirable.

Dr. Stedman's Gift to Columbia.—Dr. Thomas L. Stedman of this city has presented to the library of Columbia University a collection of a hundred peculiar books. They include christomathies, collections of folk songs and phrase books in Russian and Modern Greek, several Chinese books, including a Chinese-Russian dictionary, lithographed from the author's manuscript, some old Arabic and Turkish grammars and a number of works on Volapük and other artificial languages.

New York State Medical Association.—This body, as already announced in the Medical News, will hold its annual meeting next week, October 15th, 16th, 17th and 18th, at the New York Academy of Medicine. A meeting of the Council will be held Monday, October 15th, followed by a meeting of the Council and Fellows. The regular general meetings will open Tuesday, October 16th, at 10 A. M. The feature of the first day will be a "Symposium on Obstetrics," in which Drs. E. P. Davis of Philadelphia, Austin Flint, Jr., Geo. W. Jarman, John E. Weeks and William R. Pryor will take part. In the evening at eight o'clock there will be a "Symposium on the Blood" in which Drs. E. K. Dunham, Leon T. LeWald, Alfred Stengel, C. Y. White, Joseph C. Bloodgood and H. C. Gordinier will take place. The President's Address will be read Wednesday and in the afternoon at two o'clock there will be a "Symposium on Tuberculosis." This will be opened with a general paper by Dr. Victor C. Vaughan of Ann Arbor and will be discussed by Drs. Jonathan Dwight, Charles Stedman Bull, Seymour Oppenheimer, John A. Fordyce, and Samuel Alexander of New York, Drs. Maurice H. Richardson and E. H. Nichols of Boston, and by Dr. John G. Clark of Philadelphia. The program in fact is especially attractive. The Trunk Line Association has granted a reduction on the certificate plan, of one and one-third fare to those coming to the city, which reduction applies to their friends and families.

Defence of the Free-Clinic System.—In the current issue of *Charities* is printed a letter from the Rev. David H. Greer, rector of St. Bartholomew Church, in defence of the free clinics which we believe to be most falsely founded. This letter was occasioned by a statement from Dr. S. A. Knopf that there is a serious abuse of the free-clinic system in New York City, fully one-half of the population receiving all medical treatment in this way. In his reply, Dr. Greer says in part: "The statement quoted by Dr. Knopf, and which has been time and again repeated, about one-half the people of New York receiving free medical treatment, is not based in my judgment upon exact statistical information. We are reported, for instance, as having treated over 25,000 cases last year at St. Bartholomew's. The fast is, however, we only treated about 6000, many of whom were treated three or four times; and even these 6000 were not all new cases, but came to the dispensary at intervals of several months, and yet every time they came they were counted, and counted, too, in every department of the dispensary in which they made application." Dr. Greer further maintains that the average wage-worker in the city cannot afford to pay for treatment by a reputable physician, as the charges are too exorbitant. Comment upon this last statement is superfluous. One sees in it one of the reasons of Stevenson's opinion of some of the clergy noted in our editorial columns. If Dr. Greer would take the trouble to really inform himself he can readily ascertain the fact that practically every statement in Dr. Knopf's letter to the *Times* is *true*.

Obituary.—Dr. William Webb Browning died Wednesday, October 3d, from a stroke of apoplexy, at his home at No. 155 Reid Avenue, Borough of Brooklyn. He was stricken while riding along the Eastern Parkway with his daughter in an automobile. Dr. Browning was born in Metuchen, N. J., in 1852. He was graduated from Yale in 1873, and in 1875 was graduated from the Columbia Law School. After practising law in this city for seven years, he entered the Bellevue Medical College, from which he graduated in 1884. In 1895 Yale College conferred upon him the honorary degree of A.M. Dr. Browning held two professorships in the Long Island College Hospital—the chair of anatomy and the chair of clinical orthopedics. He was a member of the Kings County Medical Society and the American Academy of Medicine. He leaves a widow and six children.—Dr Marie Upton Hanford died from cancer on October 6th at her home, 178 South Fifth Street, Brooklyn. She was the daughter of the late Gen. Emory Upton, United States Army, and was born in Batavia, N. Y., sixty-three years ago. She was married in 1871 to Dr. F. C. Hanford, who has been practising medicine in Brooklyn and New York for fifty-seven years. Mrs. Hanford was graduated from the New York Hospital for Women twenty years ago, and was well known through her charitable work among the dispensaries for the poor.

PHILADELPHIA.

Obituary.—Dr. Crawford Irwin, one of the most distinguished physicians of Central Pennsylvania, died at Hollidaysburg, October 7th. He was twice president of the State Medical Society.

Ambulance Wrecked.—The ambulance of Hahnemann Hospital was completely wrecked October 5th by colliding with a trolley car. Both the surgeon and driver escaped with slight injuries.

Large Bequest.—Charles Edward Orme has left an estate of $50,000 to the Episcopal Hospital. The income is to support as many free beds as possible.

Indictment of Faith Curists Changed.—On August 31st the Grand Jury indicted Sheets and Sellenberger, keepers of "The Beulah Orphanage," for the murder of a baby seven months old. The October Grand Jury has changed the indictment to one of manslaughter.

Resignation of Dr. Neff.—Dr. J. S. Neff has resigned from the Board of Charities and Correction. Dr. Neff, who is also medical director of the Jefferson Hospital, refuses to confirm the report that he resigned because of the mayor's attempt to revolutionize the Department. W. J. McLaughlin, a retired banker, succeeds Dr. Neff.

Reported Lockjaw from Vaccination.—Two deaths from vaccination are reported from Erie, where smallpox has lately been prevalent. The last is said to be due to lockjaw. The girl was vaccinated two weeks ago and attended school regularly after it.

Clinics at the Almshouse.—At the suggestion of Dr. Shoemaker, President of the Board of Charities and Corrections, the clinics are to be made more attractive at the Philadelphia Hospital. This is for the benefit of the medical students of all the colleges in the city. Members of the visiting staff are also to be allowed the use of the wards for small classes in bedside instruction.

Hospital Sued.—John F. Matthews and wife have instituted a suit against the Presbyterian Hospital and a physician connected with it because of the death of their son. The boy was injured in a carriage accident, but was allowed to go home after an examination. Shortly afterward he was admitted to the hospital when serious symptoms developed, and he soon died.

The Angiotribe.—At a meeting of the Obstetrical Society, October 4th, Dr. E. E. Montgomery reviewed the methods of hemostasis in abdominal surgery. While in Paris the past summer he saw Doyen operate and use the angiotribe. This instrument he uses to crush the tissues and make a groove for a ligature. Montgomery believes the instrument to be useful in dealing with thick tissues, but would always put on a ligature in addition. He advises catgut rather than silk ligatures, having used them for several years without their giving trouble.

Spinal Cord Anesthesia.—Two operations by this method of anesthesia have been done in this city recently, both being reported at the College of Physicians October 3d. Dr. W. W. Keen's patient was a negro, aged fifty-one years, who had a large scrotal hernia. It was feared that reduction of the mass would impede respiration if general anesthesia was used. Eucaine was injected into the cord, Dr. Keen preferring this because it is more readily sterilized than cocaine and because it is less toxic. Half an hour after the injection was made nausea and vomiting began. The operation was completed in one hour and the man did not complain of pain, although a prick of the skin at the ankle was readily felt. The patient is now doing well, there being no unfavorable after-symptoms.—Dr. W. L. Rodman reported the removal of a bursa from under the semimembranous muscle, spinal anesthesia being used because of damaged kidneys and the prone position. There was decided nausea and vomiting five minutes after the injection, cocaine being used. Anesthesia was absolute. The patient's pulse was only 52 per minute one hour after the operation, but was strong and the man felt comfortable. These two operations, both done the same week, were the first to be done by that method in this city.

CHICAGO.

Chicago Surgical Society.—The annual meeting of this Society was held at the Chicago Athletic Club, October 4, 1900. The following officers were elected for the ensuing year: President, Dr. Christian Fenger; Vice-President, Dr. J. B. Murphy; Secretary, Dr. Daniel N. Eisendrath, reelected; Treasurer, Dr. E. J. Mellish.

Vaccination Reports.—Reports from the physicians assigned by the Department of Health to vaccinate the general public were recently received, and they show a flattering condition of success. About 140 physicians have been given the office of city vaccinator. The aggregate number of vaccinations is larger than ever before during a period when smallpox does not prevail. But what is most gratifying to the health officials is the fact that there is much less opposition than ever before. Glycerinized virus is used, which is said to be absolutely free from any extraneous germs, and there is no possible danger of any ill results, such as were encountered formerly.

Revocation of Certificates.—In a decision handed down October 4th, the Appellate Court ruled that the State Board of Health, under the act of 1899, has no power to discipline medical practitioners licensed before July, 1899, or to revoke

physicians' certificates issued prior to that date. The ruling is made in the case of Dr. William Frank Ross, who was licensed as a doctor in 1895 and who was summoned before the State Board of Health in September, 1899, to show cause why his certificate should not be revoked for alleged unprofessional conduct. Counsel for the State Board of Health argued that if the act of 1899 limited the powers of the Board to certificates issued after its going into effect, then under the previous act of 1877 it still retained authority to discipline physicians. After discussing the contentions advanced, Judge Windes, who voiced the opinion of the Reviewing Court, ruled that the act of 1877 was repealed by the later act of 1887, which itself was expressly repealed by the act of 1899, thus leaving the Board of Health acting solely under the 1899 act. Before the appeal to the Supreme Court was prayed, the matter was placed before the Board of Health. It may be that an attempt will be made to procure the passage of an adequate statute by the Legislature instead of a reversal of the Appellate Court ruling.

Appointment of Dr. Lemke.—Dr. August F. Lemke has accepted a position in the department of Didactic Medicine in the Northwestern University Medical School.

Changes in the Faculty of the Chicago Policlinic.—Dr. Norval H. Pierce has accepted the Chair of Otology in this institution, Dr. Otto T. Freer, that of Laryngology and Rhinology.

Commencement Exercises of Rush Medical College.—Eleven candidates received the degree of Doctor of Medicine at the commencement exercises of Rush Medical College, held October 5th. Formerly these exercises were held in June, but the affiliation with the University of Chicago has caused a change in the date. Dr. L. F. Barker delivered an address on "The Study of Anatomy," in which he reviewed the wonderful progress in anatomy and other branches of the healing art during the last century, and spoke of the great improvement in the methods of teaching in the medical schools of our time. Dr. Frank Billings, the Dean of the Faculty, read his annual report. He pointed to the success of the quarterly system, which was introduced two years ago, and said that the number of students during the summer course was nearly double that of last summer. He referred to the higher standard required from applicants for admission to the college, and said that nearly fifty per cent. of the applicants were rejected. He expressed great hopes for the success of the elective system.

Epidemic of Diphtheria.—Dr. C. S. Nelson, Special Inspector of the State Board of Health, and Dr. M. M. Hill, Bacteriologist, sent to Rosehill, Jaspar County, Illinois, to make a detailed examination of an alleged epidemic of diphtheria, made a report to the State Board of Health October 5th. There were 100 cases of diphtheria and 30 deaths, no quarantine, and the disease was spreading rapidly. One case had been diagnosticated as tonsillitis by a physician. Rigid quarantine will be established.

GENERAL.

Proposed Legislation for Inebriates in Ontario.—Before the conference of the Canadian Charities and Correction Convention, which assembled in Toronto lask week, Dr. Gilbert Gordon, President of the Toronto Medical Society, outlined the plan for dealing with the inebriate class of the community. Legislation is to be introduced into the Ontario Parliament at the next session. The Government will be called upon to appoint a superintendent, whose duty it will be to organize the medical treatment of this class on the probation system. In cities of 20,000 or over a probation officer will be appointed who will have the supervision of inebriates under suspended sentence. Wards will also be arranged for in the General Hospitals of the province. The scheme has already been endorsed by the Ontario and Canadian Medical Associations.

Wonderful Beard.—Samuel Fries, a farmer of near Steinville, Lehigh County, Pa., who raised a beard nearly six feet long, died October 2d. He seldom displayed his whiskers, which he kept concealed beneath his coat.

An Insect Which Excretes Camphor.—O. F. Cook (*Science*, October 5, 1900) describes a small insect, Polyzonium rosalbum, which excretes a substance smelling strongly of camphor. It is the only instance known in the animal world.

Modifies Its Quarantine.—The Louisiana Board of Health has modified its quarantine against Central American ports, and vessels from all ports in the Gulf and Caribbean Sea where no yellow fever prevails will be allowed to come to New Orleans without quarantine detentions after October 15th.

Helen Keller at Radcliffe.—At the recent entrance examinations at this college Helen Keller, the phenomenal deaf mute, passed with distinction.

Death of Plague at Cardiff.—A sailor who recently arrived on the Tyne from Rosario, Argentine Republic, became ill. He went to Cardiff, Wales, where he died October 7th of the bubonic plague.

A German Departure.—The Berlin president of the police force has recently appointed Dr. Agnes Hacker medical officer to the female prisoners in the Prussian penitentiary.

No Doctor for Sick Child.—The daily press reports a case of typhoid in East Orange which no regular physician is attending, and the patient, a child, is being attended by Christian Scientists.

This much Health Inspector Bowman and Health Officer Winthrop Mitchell admit. They refuse to tell the name or the residence of the sick child. It is said that no law exists which allows a Board of Health to interfere in a case where a regular physician is not employed. The only provision that can be taken advantage of is in case the patient dies without having received treatment from a doctor. Christian Scientists are not vested with the right to sign burial certificates.

New Color Blind Test.—The judges of the Paris Exposition have awarded a first prize gold medal to Prof. E. W. Scripture, head of the Psychological Department of Yale University. Prof. Scripture sent to Paris as an exhibit from the United States Government a machine for testing color-blindness. The machine has proved all other methods for making such tests fallible and is likely to become the official testing machine, not only of this Government but of the world. It has attracted much attention in Paris and was proved to be a necessity in the navy, where to be able to properly distinguish signals is absolutely necessary to an official.

New Chair for Prof. Chittenden.—Prof. Russell H. Chittenden, Director of the Sheffield Scientific School, has been elected professor of physiology in the Yale Medical School. He recently declined an offer to take charge of the Department of Physiological Chemistry in Columbia University. His relationship to the Sheffield Scientific School will not be affected. Dr. Yandell Henderson, who has been an instructor in the Sheffield Scientific School, will be Prof. Chittenden's assistant in his work in the medical school.

Typhoid Fever at Newport.—An epidemic of typhoid fever in Newport is now manifest, and it has reached such proportions that a special meeting of the Board of Aldermen was called October 8th, to take action in the matter. Newport has no Board of Health composed of medical men, the Aldermen acting in that capacity, and on this account it is much harder to deal with such cases. There are probably fifty cases of the fever in the town. The Newport Hospital is full and cases are waiting for admittance. So great has been the demand for hospital accommodations that the Aldermen to-day appointed a committee to arrange for the establishment of an emergency hospital. It was also directed that the city water be examined. A great many of the cases are of a mild type. Cases have appeared in all parts of the city.

Yellow Fever in Havana.—The officials of Cuba are considerably alarmed over the yellow-fever record in Havana for September. It has not been so large in two years, and exceeded the previous month, when 220 cases were reported. The September record is 269 cases. The number of cases on September 1st was 89, and a report just received from the War Department shows that the disease increased rapidly, reaching 269 on September 30th. Fifty-two of those stricken died, while 218 recovered and were discharged from the hospital. On September 30th 88 patients were under treatment. By October 2d this was increased to 96, there being 15 new cases on that day. Four were discharged and three died. Of the 96 cases 19 were Americans. The report says: "The disease was more general among the Americans during September than any time during American occupation of the island. While the death-rate among the Americans was small, the total death-rate was 20 per cent. Non-immunes as well as others have been stricken. The outbreak has not been confined to any one locality. It has appeared in all parts of Havana, including all the suburbs." Two cases have appeared at Gen. Wood's headquarters in the palace. The first was that of Mr. Omer C. Blizzard, Gen. Wood's stenographer; another was a watchman at the palace.

Concentrating Consumptives.—*The New York Times* says that the largest plan ever known for a concentration of the consumptives of this country to one section came to light October 4th in Fort Stanton Reservation, 150 miles south of Santa Fé, where the United States Marine Hospital for consumptives is located. The Ancient Order of United Workmen made application to the Government for permission to erect a sanitarium for consumptive members on the reservation, and the Woodmen, Odd Fellows and other secret orders followed rapidly. A plan to allot each State desiring it sufficient ground for a sanitarium is being seriously considered, owing to the prevalence of tuberculosis in portions of the East.

Koch and Malaria.—The daily press so rarely comes within many miles of the truth in medical matters that it is a pleasure to find an accurate summary of the recent Koch headlines in our esteemed contemporary, *The New York Times*. It says: "As might have been expected from the previous course of Dr. Robert Koch, there is not a word in the announcement of his successful investigation of the cause and cure of malaria to indicate that he is not alone in this field of study, or to hint that he has simply been following a line carefully marked out long ago by other scientists and since developed by them with an industry and ability at least equal to his own. This is not to say that the Berlin bacteriologist is neither industrious nor able; he is both to a high degree; but his reputation—out of Germany, at any rate—is that of a man not less businesslike than scientific, and he has been charged before now with a somewhat unprofessional tendency to monopolize glory and profits in a way not quite compatible with delicacy of sentiment. His recent labors in China have apparently brought nearer to the point of actual demonstration the theory that malaria and mosquitoes are closely related, but that is not his theory, except by adoption, and he might well say more than he does about the English surgeon stationed in India who

originated it, and about the men of the same and other nationalities who have done so much to lend it credibility. The omission, however, is of no great consequence. If malaria can be prevented or cured, it makes little difference by whom it is done, and little, in a practical way, whether or not the incidental glory is justly distributed. Success means the multiplication by two or three of the portion of the globe on which civilized men can live, and it will do more than any other one thing to lighten the task of carrying law and order through the region bounded by the two tropics."

German Milk Regulations.—According to an official report from the United States Consul at Leipsic, Germany, the municipal council of that city has recently adopted new and stringent regulations governing the local milk supply. An elaborate inspection service is provided and inspectors are authorized to take samples, not to exceed one-half liter in quantity, at any time or place until the commodity is in the hands of the actual consumer. Compensation is allowed for samples that pass the test of analysis. All cans and bottles containing milk must be so labeled as to show the quality of their contents according to the classification noted below. Other regulations provide for the inspection of all cows (including the tuberculin test) and the persons having the care of them, all stables and premises on which milk is stored or offered for sale. Milk for children may be sold only by producers who obtain a special permit for such traffic and comply with certain additional sanitary and hygiene requirements. The four grades of legally salable milk are as follows: (1) Full milk, first quality, which must contain at least 3 per cent. of fat and must have a specific weight of 1.028-1.034 at 15° C.; (2) full milk, second quality, which may contain less than 3 per cent. of fat, but the exact proportion must appear on the label; (3) skimmed milk, which must contain at least 1 per cent. of fat and must have a specific weight of 1.032-1.038 at 15° C.; (4) milk for children, which must be full milk, first quality, obtained from cows whose food and condition of health are directly under the constant supervision of a veterinary surgeon, acting under authority from the city officials, the said cows having no serious ailments. Prohibited is the sale of milk from animals afflicted with disease, especially tuberculosis, anthrax and distemper; from cows during the eight days immediately subsequent to calving; from localities in which typhus or cholera epidemics exist; and such as is bitter, slimy, nauseous, spoiled, abnormally colored or adulterated. When adulteration is suspected the samples secured may be compared with others obtained at the stables directly from the same cows. For the purpose of preliminary examination each inspector is required to have Quevenne milk scales and a Feser lactoscope, the former to determine the specific weight and the latter the fat percentage. Before applying these tests the milk is to be well mixed, by the dealer himself if he prefers. If the milk fails to correspond with the label on its container, a half liter sample is to be taken for chemical analysis, a similar sample to be given, sealed, to the dealer. Unlabeled milk is considered full milk, first quality. If an inspector has good reason to believe that milk which stands the tests as to specific weight and fat is offered for sale in violation of the regulations concerning cleanliness or adulteration, it is his duty to confiscate it and lodge a special complaint against the owner.

The Juice of the Oyster.—It may not be generally known, says the *Sanitary Record,* that the fluid which surrounds the oyster bears a closer analogy to the gastric secretion than anything else in nature. In addition to the solvent properties of this fluid it is not without its nutritive properties. Consequently as little as possible of the juice should be lost.

CORRESPONDENCE.

SEPSIS AND TOXEMIA.

To the Editor of the MEDICAL NEWS:

DEAR SIR: I am much indebted for your consideration and will say in reply to the kind remarks of Dr. Eshner that the intent of my paper of September 22d was to qualify the meaning of the term "sepsis" and "septicemia" in connection with the acute infectious diseases, if not its use. As he so justly remarks the terms have hitherto been used in a most vague and indefinite, if not ambiguous, manner. But if the specific infective organisms are recognized as having inherently the quality of invading the tissues through (possibly) some special toxic influence developed according to environment, *then* the term "sepsis" becomes qualified in these diseases, more "definite" and not "ambiguous," since the condition is the result of the development of an inherent quality. It becomes modified to the extent that it no longer occupies an undetermined place, but is the *opposite* of "toxemia," not bearing, it is true, the sense of harm to the individual *because* of the presence of the bacteria, since symptoms in these cases depend upon the continued elaboration of toxins.

"Intoxication" is a term applicable to symptoms arising from a number of causes, but when used in relation to the infectious diseases it is qualified and well defined; and so does the term "sepsis" take on a new definition in such connection. "Bacteremia" is rather ill defined and does not convey the idea that the clinical symptoms of sepsis are present. The term "infective," as applied to this condition of invasion of the blood by the specific germs by Baumgarten, is not appropriate, since it is also applied to the influence of the primary colony of the germ, and should not be used as a term distinctive of the specific sepsis.

EUGENE WASDIN,
United States Marine Hospital Service.

Buffalo, N. Y., October 5, 1900.

ELIMINATIVE AND ANTISEPTIC TREATMENT OF TYPHOID FEVER.

To the Editor of the MEDICAL NEWS:

DEAR SIR: In the reported proceedings of the Canadian Medical Association meeting published in the MEDICAL NEWS there appears under the heading of "Eliminative and Antiseptic Treatment of Typhoid Fever" a brief abstract of my paper. I had in that paper protested against the misrepresentation I had received in certain quarters. Your reporter furnishes an apt illustration of what I complained of, and in this short abstract has managed to distort and misstate what I said to an extraordinary degree. For example, I am reported in this abstract as holding "the opinion that the drainage from the intestinal wall following upon the action of a purgative, such as calomel and magnesium sulphate, would tend to get rid of some of these bacilli in the *intestinal walls,* but would not effect their exit from the liver, etc."

I had in the first part of my paper quoted from the recently published Gouldstonian Lectures, delivered before the Royal College of Physicians of London by Dr. P. Horton-Smith, on "Typhoid Fever and the Typhoid Bacillus," to show the correctness of my contention of seven years ago that the specific bacilli were present in the intestinal contents during the first days of the fever —not absent from the intestinal contents as has been asserted—and consequently that the soundness of my theory of their being swept out by the action of purgatives, thus limiting the infection of the body and of the glands in the intestinal wall, became perfectly obvious. Then followed the paragraph referred to, which I shall quote in its entirety:

"Elimination must not be confined to simply clearing out the intestine, but must apply to a much wider process; the clearing of poison from the body by way of the intestine either in the toxic bile or contained in the serous fluid poured from the intestinal wall.

"It is amusing after having made so many explicit statements and having drawn attention so many times to this feature to find Prof. Osler gravely pointing out to his readers 'that, unlike cholera, the typhoid bacilli are not confined to the intestine, but are to be found in the spleen, intestinal glands, etc., and consequently that they cannot be dislodged by the use of purgatives.'

"I shall again be explicit in the statement that the eliminative plant of treatment does not contemplate removal of bacilli from the spleen, intestinal wall and various tissues of the body, but does contemplate elimination of *bacilli and poisons from the intestine* and of *toxin from the body by way of the intestine.*"

A second example: I am made to say that I had never had a fatal hemorrhage and that I had *but few perforations.* What I did state, after pointing out that twenty per cent. of the mortality of typhoid fever had been attributed to perforation and hemorrhages, was that "in my own experience I had never had a fatal hemorrhage and but few hemorrhages, nor have I had in all these years a *single perforation.*"

I am sure you will agree with me that it is most unfortunate when mistakes like the above occur, utterly false impressions are received by an immense number of readers, and it frequently happens that this impression remains since many who have read the report will fail to notice the correction. W. B. THISTLE.

171 College Street, Toronto, October 4, 1900.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, September 29, 1900.

THE OUTBREAK OF PLAGUE IN GLASGOW—HOW THE PLAGUE WAS FOUGHT IN SYDNEY—THE SOUTH AFRICAN HOSPITAL COMMISSION—EVIDENCE OF LORD ROBERTS—DEATH FROM GAS-POISONING—DANGEROUS CHANDELIERS.

FIVE new cases of plague have occurred in Glasgow so that the hope expressed in my last letter that the epidemic had spent itself has not been quite justified. There are now 22 cases. Four of the new patients are members of one family, consisting of mother, grown-up daughter and two children. The family had associated with persons suffering from plague. The fifth patient is the wife of a man employed in the hospital. Dr. Cantlie, whose experience in the East especially fits him for the task, has been deputed by the *British Medical Journal* to inquire into and report on the outbreak. He states that the steps taken as regards segregation of "contacts," disinfection of premises, and treatment and isolation of patients, leave nothing to be desired. There is no evidence to show how the people in the house in which the outbreak started became infected. A peculiarity of the outbreak is that it occurred at some distance from the harbor, and that the infected area is not opposite the part of the river where ships lie. Infected rats may have found their way along the sewers, but of that there is no evidence; moreover, if rats had been the cause a more general outbreak would in all probability have occurred. There are several types of plague—bubonic, pneumonic, intestinal, typhus and fulminant (which causes death without characteristic signs or symptoms). The original cases in Glasgow were of the intestinal and pneumonic types, and simulated typhus and typhoid fever, and simple pneumonia, so that only by bacteriological examination could their nature be determined. It is highly credible to the Glasgow faculty that the disease was so speedily recognized.

In connection with the Glasgow outbreak a report by the special correspondent of the *Lancet* on the Sydney outbreak is of interest. Sydney contains a population of 456,000, all being whites except 4000 Chinese. The first case appeared in

January, and up to July 28th there have been 302 cases and 102 deaths. After the appearance of the first case it was requested that all cases of illness of a doubtful character should be reported to the sanitary department. Such cases were examined and diagnosed by a staff medical officer. On the appearance of the second case the coroners were desired to report all uncertified cases of death in which there was suspicion of plague, in order that examination of the bodies might be supervised and a safe burial ensured. Haffkine's prophylactic serum was used to inoculate the staff, "contacts," and persons inhabiting the parts of the city which appeared to be dangerous. Posters and pamphlets were used to disseminate information on the plague. Those parts from which numerous cases had been removed were dealt with under the quarantine law, surrounded by a guard, and thoroughly cleansed. A staff was organized for the destruction of rats. The sewers were frequently fumigated with burning sulphur, which killed some rats and drove large numbers to the sewer-mouth, where they were destroyed. No vessel trading with Sydney was allowed to communicate with the shore at other ports unless it had been fumigated and the rats destroyed. Vessels were forbidden to lie at wharves except under regulations calculated to prevent the landing of rats from them. A part of the maritime quarantine station was equipped and utilized as a plague hospital. As soon as a case of plague was diagnosed 40 cc. of Yersin-Roux serum were administered subcutaneously. On arrival at the quarantine station protective inoculation was offered to all "contacts," but was rarely accepted. They were deprived of their clothes and given clean ones. Their clothes were restored to them after disinfection and after five days they were discharged. The bodies of persons who died from plague were enveloped in a sheet soaked in sublimate solution and placed in light coffins with watertight joints. The coffins were enveloped in coarse sheeting also soaked in sublimate solution. They were buried in a sandy soil on a slope falling toward cliffs above the Pacific.

The Hospital Commission has held further sittings at Bloemfontein. General Kelly-Kenny paid a tribute to the orderlies who carried a number of Boer wounded across a river in which they were up to their armpits in water—a service which was purely voluntary. Lord Roberts gave valuable evidence showing the difficulties of transport. He said that on entering an unknown, sparsely populated, and hostile country, it was absolutely necessary to take large food supplies and the number of mules, horses, and forage for these was limited. Rapid movement was possible only by cutting down the equipment of the field hospitals and other details. In Bloemfontein everything possible was done for the sick and an unlimited order was given to commandeer everything obtainable. The enormous difficulties which had to be overcome were shown by the fact that from March 13th, when Bloemfontein was reached, to Mach 28th not a single truck was able to cross the Orange River and no food was obtained from the base. For sixteen days therefore there were no supplies and but few medical comforts obtainable, although 40 trucks or 400 tons of food were required for men and animals. From March 29th until April 7th the trucks sent to Bloemfontein were 105 less than the number required for the daily supply. From April 7th to 17th 503 trucks arrived—11 less than the number necessary. The troops were only just fed and not one day's reserve was accumulated. Sixty-two trucks with hospital stores came in during that period. Every day's delay in Bloemfontein made matters worse and food for further advance had to be accumulated. At Kroonstadt everything obtainable was commandeered and ladies came crying that mattresses and beds were taken from under them. Lord Roberts thought that no blame attached to the home authorities in reference to the supply of stores and equipment. The campaign had been extraordinarily difficult from the hospital point of view and in his opinion the Royal Army Medical Corps, assisted by the civilian surgeons, had met the difficulties magnificently.

A death from gas-poisoning in Birmingham shows the danger of the "gas chandelier" or water-slide pendant, which the *Lancet* severely condemns and thinks no prudent householder should allow in his house. The water is always evaporating and the need of replacing it is easily forgotten. Further the sliding tube and chains supporting the weights easily become defective, allowing the bracket to drop below the water seal and the gas to escape. This is what actually occurred in the present case. The chandelier was in such a bad condition that one of the chains was tied with string while the other had been mended with wire in three places. A man and his wife retired in good health. They awoke early in the morning with headache. The woman went to sleep again and remembered no more. The man appears to have left the bed and fallen across it. About 9 A. M., as they could not be aroused, the door was burst open. The man who entered the room declared that the smell of gas was not particularly strong, and although he could not arouse the sleepers the suspicion that they were asphyxiated did not occur to him until a later visit when he made another unsuccessful attempt to awake them. The man was past all aid and his wife was only snatched from death by several hours of artificial respiration. It appears that the deceased had only just entered into possession of the house. His wife said, "How the gas smells," and he replied that it would be repaired next day. The modern method of mixing coal gas with carburetted water gas greatly increases the proportion of CO and therefore produces a more poisonous gas. This fact accounts for the increased number of cases of gas-poisoning which have occurred of late. These cases have been unusually fatal and have excited much popular attention.

OUR MADRID LETTER.

[From Our Special Correspondent.]

MADRID, September 20, 1900.

MEDICAL MADRID AND THE NEXT INTERNATIONAL MEDICAL CONGRESS—RAMON Y CAJAL—HIS UNIVERSITY WORK—SALARIES OF UNIVERSITY PROFESSORS.

THE next International Medical Congress is to be held down here in the Spanish capital and suggests the thought that some notes on medical features of the city would be of interest to readers of the MEDICAL NEWS. About medical matters in general there is not much to be said. The Spanish Government has not been very liberal in its appropriations for medical purposes during recent years and ten years is an age in the history of modern hospitals, while half a century brings one back almost to barbarism in the matter of hospital arrangements and appointments. The hospitals of Madrid are practically all old and old-fashioned. They remind one very much of the older hospitals in Paris. The wonderful thing is that in such seemingly unsuitable quarters excellent surgery has been done in recent years. Spanish surgeons accomplish successfully all of the operations performed by their colleagues across the Pyrenees. In the department of abdominal surgery particularly they have been bold and singularly successful.

The Medical Department of the University of Madrid possesses a large building with a handsome facade. The clinical department is, however, very old and ill arranged. A magnificent set of balconies enclosed in glass forms a notable exception in the midst of the universal lack of invitingly suitable quarters for the sick. These enclosed balconies are and have been for centuries a feature of Spanish life in general. Here in the hospital they make an ideal place for tuberculous patients of which there is no lack among the Spanish population in spite of the reputation the Peninsula generally bears as a resort for the consumptives of other countries. The teaching department of the University is in a more recent building, but is sadly hampered for lack of room. There is the promise that within the next year the Spanish Government will appropriate a considerable sum for the enlargement of this building. It is considered almost certain that the new departments will be finished before the holding of the International Congress. These new structures will furnish suitable places for the holding of the section meetings and for the varied business of the Congress, the management of which is becoming with each succeeding session a more and more difficult problem.

It is in the present unsuitable quarters that Ramon y Cajal has worked for the last ten years. In spite of the discouragement of his surroundings he has succeeded in continuing here the investigations begun at Valencia and Barcelona that so deservedly won for him the prize of Moscow, at the recent International Medical Congress at Paris. His professional position gives the best possible idea of the present state of medical teaching in Spain. It serves to show particularly the difficulties under which medical teaching is carried on and makes truly wonderful the reasonably high average of success that is attained by it; for the average Spanish practitioner is not below his confrères of other countries.

Prof. Ramon y Cajal is primarily the teacher of histology. His department includes, however, all works involving the use of the microscope. He teaches pathological as well as normal histology. Moreover, it is to him the students look for their instruction in bacteriology. To his department are sent from the general hospital all the excreta—sputum, feces and urine—that are to be examined microscopically for the wards and for the clinical teaching in the medical departments. It is under his direction that are made the Widal test and all the blood examinations. This might seem sufficient for one man, but in addition to doing all the microphotography of the hospital, it is under his supervision that all ordinary photographs of patients before and after operations and the like are taken. In this part of his work Prof. Cajal takes great personal interest. He is and has been for twenty-five years an expert photographer. He was one of the first in Spain to make the old collodion plates that succeeded the original daguerreotypes, and even dealers applied to him for plates in the early days because of his skill. Like many of the successful medical investigators of the century, Claude Bernard-Schwann, Brown-Séquard, and others, Cajal is evidently what we call in America a "handy" man.

Despite the burden of labor on his shoulders, Cajal's only complaint is that he has not proper facilities for his profesional work nor for his original investigations. All of his labor must be accomplished in very cramped quarters. Besides, there is the question of money. The allowance for laboratory work made out of the University budget is so small that there is practically no question of experimental work upon animals. As it is, most of Cajal's investigations have been conducted entirely at his own expense.

It is interesting in this connection to note the amount University professors are paid as salaries. I was credibly informed that at Madrid the holder of a full University professorship receives during the first five years of his professoriat 4000 pesetas a year; that is supposed to be $800 per year; but a peseta, owing to the state of Spanish finance, is really not worth 20 cents, in fact, barely 15. This reduces the salary to $600 a year. Those who think that living is cheaper in Spain than in America should visit the country and be convinced that, on the contrary, all the ordinary necessaries of life are really dearer. After each successive five years of teaching the

salary is raised 500 pesetas, that is, about $80. The salaries in the provinces at the Universities of Valencia, Saragossa and Barcelona, where Cajal taught before being called to Madrid, are, as might be anticipated, even smaller than those at the capital.

That Cajal has accomplished the work he has is under the circumstances a never-ending surprise. It has not been without leaving its traces, however. He looks older than his forty-six years and has not been as well as he should be during the past year or two. Poor health has delayed the publication of his second volume on the minute anatomy of the nervous system. The work is now practically complete, however, and will shortly be published. The recent award of the prize of Moscow was a most welcome acknowledgment of the worth of his labors, and the 5000 francs will prove a substantial reward. It has left him as modest and unassuming as before, kindly, cordial, most grateful for his reception in America last year. He looks forward to much more substantial allowances for medical work from the Spanish Government now that its colonial burdens are transferred to broader shoulders.

NECROSIS OF THE UTERINE CERVICAL STUMP—PREVENTION OF UNTOWARD RESULTS IN VAGINAL AND ABDOMINAL SURGERY—DYSMENORRHEA.

C. Ryall, at the British Gynecological Society, July 13, 1900, showed a rare and interesting specimen of necrosis of the cervical stump after supravaginal hysterectomy. E. S. Bishop (Manchester) introduced a discussion on the untoward results of vaginal and abdominal surgery and on the best means to prevent the same. Any unfavorable outcome of an operative procedure is active in deterring future patients from seeking relief thereby early enough to do good, in increasing discouraging statistics of and disfavor toward the special operation and in more or less discouragement to the surgeon himself. His illustration was taken from hysterectomy for fibromata and the chief difficulties cited were: (1) Fatality, due to delay in undertaking the operation and to sepsis. Early purgation and its importance were explained with operative technic; (2) ventral hernia, best avoided by successful asepsis, carefully placed layer sutures and celloidin; (3) intestinal and omental adhesions, making careful reconstruction of the potential peritoneal cavity necessary; (4) vaginal prolapse again indicating restoration of the layers of the pelvic floor; (5) persistent sinuses resulting from imperfectly sterile sutures and applied drains; (6) various other accidents.

H. Smith preferred subperitoneal hysterectomy to panhysterectomy and an incision about one inch to either side of the linea alba to prevent ventral hernia by making more layers to suture.

C. Martin (Birmingham) in contrasting the various methods of hysterectomy said the cervical stump is of no service and only theoretically prevented vaginal prolapse. He never yet had seen such a result of panhysterectomy. He had always been opposed to buried sutures as predisposing to ventral hernia, but, having adopted the method of Greig Smith of boiling chromic-acid gut in xylol and absolute alcohol, he had not yet had any stitch abscesses from buried gut. The three-layer method of suture he considers best. Macnaughton-Jones prefers the supravaginal method for ablating the uterus.

E. T. Davies (Liverpool) said fibroids often give no symptoms and are of importance only from an esthetic point. Hence it is not easy to determine when to operate. Baer's operation is his preference, next panhysterectomy.

C. Ryall considered ventral hernia due usually to drains. He always drains through the pouch of Douglas or by the method of Muscatello. Stitch abscesses appear due to infection of the hands by intestinal or neoplasm contents during the operation.

R. Bell (Glasgow) considered the danger of abdominal section due entirely to sepsis. The intestines cannot be the source of sepsis, because, if they were, why did not ordinary constipation cause it?

J. W. Draper (Heddersfield) reported fifteen cases of fibroid in his own practice where the tumors had been left. In one the ovaries were removed and in a second a pedunculated fibroid had been ablated. He thought greater conservatism advisable.

W. J. Smyly (the President) said that early operation is wise. He had seen a large fibroid forced into the vagina and suppurate, malignant degeneration and almost fatal hemorrhage result from delay. The suture method praised by any man usually is the *last adopted*. Since patients do not commonly return to the operator responsible for a hernia, each man sees few in his own practice, but many in that of other men. Celloidin does not appear to him to offer much. An aseptic wound will heal with any dressing. If infected, celloidin does little.

F. W. N. Haultain, at the Edinburgh Obstetrical Society, July 11, 1900, discussed dysmenorrhea. The pain, erroneously regarded by the lay mind as often physiological and therefore not worthy of attention, may be localized in the pelvic viscera or referred to distant organs, as the brain, stomach, heart, etc. All rational treatment must be directed to one or the other of the two causes, inflammation or congestion and obstruction. When resistance to the outflow is present, contractions take place causing cramps in the endeavor to expel the fluid or clotted blood past the flexion, tumor, stenosis or other obstruction. In inflammation the physiological congestion of the menstrual flow adds to the tur-

gidity, pain ensues and becomes relieved when the flow appears. In ovarian and tubal dysmenorrhea the pain is usually premenstrual; in uterine inflammation the congestion of the menses may increase and the pain continue through the period; in inflamed and congested ovaries the pain also precedes and pervades the whole period. In managing these cases stenosis, displacements, and tumors must all be removed. Gradual dilatation in all and incision in addition in selected cases, with curetting for concomitant endometritis, are the indications in stenosis. Any patency so gained must be maintained by after-treatment. Among drugs opium and alcohol are to be condemned, while the bromides, iodide of potassium, camphor, gelsemium, hydrastis, hot applications, hip baths, counterirritants, etc., all help. Oophorectomy may be done for advanced disease. Treatment should always be tried perseveringly.

In the discussion it was agreed that examinations of the unmarried except under chloroform had best be avoided; local treatment should in them be begun with care, but for diagnosis and cure both are necessary often. Further the following points were elucidated. H. M. Church considered prevention more important than cure; hence when girls begin this function their general health needs attention. Plenty of good food, of open-air life and of proper exercise are needed. Often the cervical mucus, supposed to prevent the blood from coagulating, is deficient. Tonics will cure this. Salicylate of soda in the rheumatic is also an excellent drug.

Professor Kynoch (Dundee) uses the tupelo tent for twelve hours; plugs with gauze for forty-eight hours and repeats. In this way very good dilatation which lasts a long time can be secured and with care sepsis avoided. Heat in douches in the recumbent position is very beneficial. An instrument devised by Stratz protects the skin from the return flow, so that a higher temperature can be used. Oophorectomy is indicated only in atrophic and hysterectomy only in atresic states.

I. Connel (Peebles) has seen many severe cases improve after marriage, relief of chronic constipation and adoption of bicycling.

J. M. M. Kerr (Glasgow) considers dysmenorrhea a symptom expressing a disease whose site and cause must be known. It is just as unjustifiable to diagnose "dysmenorrhea" as "menorrhagia." In an analysis of sixty cases he found in three abnormally small uterus, in six stenosis of the cervix, in sixteen pathological anteflexion. Iodide of potassium and salicylate of soda are often invaluable.

A. H. F. Barbour finds improving the morale of the patient, taking her mind off herself and devoting her energies to others, is of importance. S. Weir Mitchell does much by rest and food to improve the central nervous system, establishing the fact that the degree of pain depends largely upon neurasthenia, the state of the peripheral and central nervous systems. A course in arsenic and antipyrine at the time of the flow is excellent.

J. Ritchie directed attention to the cure of anemia and rheumatism as such as a preliminary step.

Holmes (Chicago) spoke of a case of defective innervation of the uterus so that parturition was painless until the vulva was reached, illustrating the fact that excess of innervation might cause increased menstrual trouble.

J. W. Ballantyne considered proper any means to learn the cause of the trouble, because without such knowledge the treatment is impossible.

Professor Saenger of Prague and Professor Fehling of Halle were elected Honorary Fellows of the Society.

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Thirteenth Annual Meeting, Held at Louisville, Ky., September 18, 19 and 20, 1900.

(Continued from page 554.)

Second Day—September 19th.

Ectopic Gestation.—Dr. James F. Baldwin of Columbus, Ohio, gave a brief account of six cases of tubal pregnancy which, added to five similar cases previously reported by him, made eleven cases in which he has made a diagnosis of tubal pregnancy and has operated before the occurrence of rupture, his experience having been in direct contradiction to the dictum of Lawson Tait that such an early diagnosis is not possible. His argument is that in a large number of cases such an early diagnosis is entirely feasible. The following points will usually be found in these cases: The patient gives a history of several years of sterility (many exceptions); she has missed a menstrual period, perhaps two of them (numerous exceptions); she has noticed some unusual pains in the pelvis, which she will probably describe as boring, griping, or colicky in character, these pains being situated usually in the region of an ovary. She has perhaps within a few days of the time of consulting her physician had a more or less irregular hemorrhage; perhaps has discharged pieces of membrane which she supposed indicated an abortion, and consults her physician with the idea that such is the case, owing to the hemorrhage and the pain and the suspicion of an existing pregnancy. On making a vaginal examination, if the conditions are at all favorable, the examiner will find on one side or the other of the uterus, or back of it, a fusiform, quite well-defined cystic tumor, about the size of a pullet's egg or a little larger. This tumor will probably be tender on pressure, symmetrical in outline, and usually

distinctly pulsating. When such a tumor is found in a woman in whom we have reasonable grounds to suspect a pregnancy, when the uterus at the same time is found somewhat enlarged and having the feel of pregnancy, but not enlarged as much as one would expect in a pregnancy of so long continuance as the history indicates, a presumptive diagnosis of tubal pregnancy is warranted, and the matter of operation should be considered. To render the early diagnosis of ectopic pregnancy possible, it is necessary for physicians to learn to suspect it and to examine patients with that suspicion in mind.

Dr. Charles A. L. Reed said that to make a diagnosis of tubal pregnancy before the time of rupture it is necessary to have the patient under observation constantly for a considerable length of time. He had encountered such a case about seven years ago, the details of which were narrated. Dr. L. H. Laidley said the only diagnosis of ectopic pregnancy he had ever made was in a case of cancer of the uterus where there was no rupture. He did not suspect the existence of the condition until he had removed the tubes and had found indications of a developing fetus within the tubes. Dr. Zimke of Cincinnati thinks the diagnosis of ectopic gestation is easy in some cases if the gynecologist has certain symptoms to guide him, namely, loss of blood, either scanty or profuse, attended with pain, and a tumor, pulsating in character, found on one or the other side of the uterus. In other instances, however, the diagnosis is very obscure, particularly in those cases in which the ectopic gestation is complicated with a normal pregnancy. Such a case was narrated. Dr. D. Tod Gilliam said that if the gynecologist could diagnosticate most cases of ectopic gestation before rupture has taken place it would prove a great boon to womankind. A distinction between tubal pregnancy and inflammatory conditions should always be borne in mind. Dr. J. Henry Carstens does not think cases of extra-uterine pregnancy are as common as the profession generally supposes. The average general practitioner with a good practice observes but very few cases in a lifetime. He spoke of the difficulty in diagnosis, and said that often when this condition is expected and operated for, something else is found.

Surgical Treatment of Uterine Displacements.—Dr. Charles A. L. Reed of Cincinnati, Ohio, read this paper. Attention was called to a couple of modifications of technic in the management of a class of cases that is happily becoming less and less perplexing. In a majority of all cases of retrodisplacements that demand operation at all, the author believes that the intraperitoneal shortening of the round ligaments is the operation of choice. It has been his habit during a number of years to effect this by making a letter-of-S fold in the ligaments and stretching them thus folded to the parietal peritoneum along the line of Poupart's ligament. This method has yielded him better results than any which he has previously tried. He has, however, become convinced that the parietal fixation of the folded ligament is not necessary for the purpose of holding the uterus in its normal position, and that the technic devised by Mann, with modifications, is all that is required to accomplish this object. Such modifications are: In seizing the round ligament with hemostatic forceps for the purpose of folding it upon itself, the tissues are frequently wounded. The use of two hemostatic forceps for the purpose of effecting the fold makes the services of two hands of an assistant necessary. To obviate these objections, which, although of minor importance, are still objections, I have devised a forceps with four flat approximating prongs, the whole being an inch across. The prongs of the opposing blades approximate with sufficient force to hold the ligament, but not enough to induce tissue necrosis, while, when approximated, they are far enough apart to permit the passage of a medium-sized needle between them. The ligament brought up into the field of operation on the finger is seized in its middle third by this instrument, which is then turned half-way around, thus effecting by a simple twist of the wrist the desired shortening of the ligament. It is then held in this position until all of the sutures are applied. These are inserted as follows: One is interrupted, one fixes the loop of ligament to the cornu of the uterus; a similar suture is utilized to fix the outer fold of the ligament; a continuous suture is then passed between the prongs of the fixation forceps, its ends being obliquely tied after the instrument is withdrawn.

A pathological condition that often exists in cases of long-standing flexions, and the persistence of which militates against the success of any fixation operation, consists in an atrophy of the concave wall and a hypertrophy of the convex wall at the point of flexure. In many of these cases, particularly when associated with diffuse fibrosis, the elongated and hypertrophied wall offers a persistent resistance to the maintenance of the normal axis of the organ. To overcome this I have, for some time, removed a cuneiform segment from the hypertrophied wall, an operation which Thiriar calls cuneohysterectomy, and which is applicable in either anterior or posterior flexions. To do this the patient is placed in the Trendelenburg position. All adhesions between the uterus and bladder, or between the uterus and other organs, are carefully broken up and rents in the serosa that may be induced thereby being carefully stitched. The uterus is then brought toward the incision by gentle but firm traction, and an ellipse of tissue about one centimeter wide and having a length corresponding to the breadth of the organ is removed from the convex side at the site of flexure. Care must be taken not to carry this dissection into the cavity of the uterus nor to wound either the circular artery or the anastomosing branches of the uterine artery. Should the latter accident occur, it is best controlled by *en masse* ligatures, passed deeply into the uterine tissue at either end of the yet

gaping ellipse. Retraction of the vessels generally prevents their isolation and closure by direct ligature which, when practicable, is always the preferable method. After all hemorrhage, except mere capillary oozing, is controlled, the margins of the ellipse should be carefully approximated and closed by a continuous animal suture passed deep into the matrix. It may be well to fortify the continuous suture with two or three interrupted ones of the same material. The uterus is then dropped back and after pausing a moment to make sure of complete hemostasis, the abdomen is closed without drainage.

Fibroma of the Ovary.—Dr. L. H. Laidley of St. Louis, Missouri, reported the following case: Mrs. H., aged twenty-nine years, married, usually enjoyed good health with the exception of almost complete deafness due to a specific disease for which she was treated some fifteen years ago. She became pregnant and was delivered of a healthy child about two months before the removal of the tumor. She had noticed a tumor in the region of the left ovary about two years ago, hard and slightly movable, which continued to grow to the size of two fists. In the development of pregnancy it was pressed upward on a line with the umbilicus and could readily be felt in her left side. There was no pain nor discomfort up to the tenth day after her delivery. She had a favorable "getting-up," but on the fifteenth day she had fever with pains, causing her to again take to her bed. These continued until the speaker saw her two months later. Upon examination he found the lungs, heart and abdominal viscera in normal condition. There could be readily felt and seen a hard, immovable tumor in the left umbilical region, with considerable ascitic fluid in the cavity. On January 20th an abdominal section was made, revealing a solid tumor adherent to the anterior wall of the abdomen. Posteriorly the folds of the bowel were adherent to that portion, the tumor was freed. It was kidney-shaped, hard, with short pedicle, one inch in diameter by two inches in length; this was ligated and the tumor removed. In tying the ligature it readily cut through its peritoneal covering, but secured the stump from hemorrhage. On examining the remaining organs, it was found that the stump of the pedicle occupied the location of the ovary; the tube remained distinct and separate from the tumor; the opposite side showed a healthy tube and ovary; there was considerable hemorrhage from the surface bleeding following the operation, but with that exception there was no difficulty encountered. The patient made an uninterrupted recovery. The tumor weighed 32 ounces and measured 6x5x3 inches. A histological report accompanied the recital of the case.

Diffuse Non-Malignant Papilloma of Vulva.—Dr. Edward J. Ill of Newark, New Jersey, read this paper and showed a specimen which he removed from a patient, sixty-eight years of age. The growth had been of over three years' standing. The inner surfaces of the vulva were thickened, at some places appearing horn-like, white and smooth; at other places there were heavy papillæ which rose considerably above the surrounding tissue and were from 3 mm. to 15 mm. in diameter at their base. The disease extended from the beginning of the vulva above down to the posterior commissure. It covered the whole vestibule except the tissue immediately surrounding the external meatus of the urethra, and was well defined, but stopped at the vaginal mucous membrane. The vulva as a whole stood out far beyond its normal elevation. The whole vulva was excised. The structure of the tumor corresponds with that usually found in papillomata of the skin. A second case was spoken of by the writer.

President's Address.—This was delivered by Dr. Rufus B. Hall of Cincinnati, who selected for his subject, "The Education of the Laity Upon Sexual Matters; When Shall They Be Taught and to What Extent?" The family physician should be the educator of the people in sexual matters, and when he gets the endorsement, and is sustained in his position by the specialist, his influence will be greatly strengthened and widened. He advises that during the last year in High School, in every school in the land, a text-book be employed embracing embryology, hygiene, anatomy and physiology, including sexual physiology, and that these subjects be taught to every student, both male and female. A female teacher should instruct the girls, and a male teacher the boys. This is the very time in life when individuals should be taught to know the functions with which Providence has endowed them, and how to care for their bodies as well as their minds. It would be a revelation to them to know that the sexual organs, in animals as well as the human race, are among the first centers to be formed and can be recognized as such early in intra-uterine life.

Private Hospitals and Their Management.—This was the title of a paper by Dr. Joseph Price of Philadelphia. The well-organized private hospital, managed by such distinguished men as Marion Sims, T. G. Thomas, Thomas Addis Emmet, William Goodell, Stone of New Orleans, and a few institutions of the present time doing the best work offer advantages that are not given by the schools or the political hospitals. The political hospital is not the only corrupt institution; a few of the well-endowed general hospitals, managed and handed down in families, to the third, fourth and even the fifth generations, are the most dangerous institutions in the medical profession. It is always a misfortune to an endowed charity or public hospital for a family to be in full possession of the funds or endowments. No one, to the speaker's personal knowledge, has ever made money and accumulated wealth out of a private sanitarium. He may make money out of the fees, but never out of the board, care and nursing of patients. The board of patients rarely pays 5 per cent. on the money invested. A good number of these institutions

have been financial failures and have closed. Private hospitals give the operator the best opportunity for doing good work.

Postrectal or Presaeral Growths.—Dr. James F. W. Ross of Toronto reported four cases of postrectal tumors, excepting the osteomata. He discussed benign and malignant growths in this region; also their etiology, symptomatology, diagnosis, prognosis, and treatment. No novice should undertake the removal of postrectal growth. It can only be done by one who has become familiar with pelvic surgery, and who is fully master of the situation. The operator must be full of resource and should be rapid in his movements. In making his incision into the abdominal wall, he should always remember that it should be made high up and enlarged downward after the position of the bladder has been ascertained. The author has had no experience with the removal of such postrectal growths by enucleation from above. He is well aware that many thoughtful, prudent and daring surgeons do not hesitate to close the abdomen when this condition is met with. What should the technic of such an operation be? Should the meso-rectum be incised close to or far away from the bowel? Should not the incision always be parallel to the vessels and not across them? How is the surgeon to accurately determine the situation of the ureter and, when discovered, how can he avoid it? How can he best guard against injury to the large vessels? In dealing with bronchial cysts in the neck the speaker has followed them almost to the spine, but has then left the deep portion of the cyst-wall, if it could be called a wall. It seems to him that he would have been forced to deal with the last case he reported of presacral cyst in exactly the same manner because the periosteum and so-called cyst-wall were so intimately connected. It would not be wise to drain such a cavity into the peritoneal cavity, but would be more prudent to attack such cysts through the post-anal tissues, perhaps with the removal of the coccyx. The solid tumors should always be attacked from the front.

Third Day—September 20th.

The Ligature and Dry Sterilized Catgut.—This was the title of a paper read by Dr. J. Henry Carstens of Detroit, Mich. The author described a modification of the Boeckman method of preparing catgut. The ligatures are prepared in the following manner: Catgut is put in ether for a few days or a week until the fat is all removed, and then cut in strips eighteen or twenty inches long. Three of these are wrapped in fine tissue paper and then placed in a small envelope. The latter is closed, and placed in a Boeckman sterilizer and subjected to dry heat for three hours. A thermometer is kept in the apparatus and the heat is kept at least 300° F. At the expiration of that time the heat is shut off, and the ligatures remain in the sterilizer without disturbance for twelve to eighteen hours, which gives any spores that may be present an opportunity to develop. The heat is again used and the ligatures are subjected to another 300° F. They are now sterile. They are put in an envelope and can be carried that way in a satchel. When ready for use the end of the envelope can be torn off and the ligature, with the tissue paper, dropped into alcohol, the tissue paper removed, and the ligature threaded and used. These ligatures are not slippery or greasy, as is the catgut prepared with different oils. The following points were emphasized: All buried sutures ought to be absorbable and absolutely sterile. Chromicized sutures are no more sterile than plain sutures. A chromicized suture is harder and remains longer in the tissues. This latter is a disadvantage. If in a special case it is desirable that a suture should remain long, dry sterilized kangaroo-tendon can be used.

Simple Methods in Pelvic Surgery.—Dr. John B. Deaver of Philadelphia read a paper with this title. Simplicity is the *sine qua non* of good surgery. It means safety, surety, confidence, neatness, and a great saving of time which is an essential factor in the success of many operations. The abdominal route is by far the more rational and therefore the best method of approaching an operation on the pelvic organs in the majority of cases, and offers several advantages that render it preferable to the vaginal. It is simpler of performance. It is safer, as the surgeon can avoid distributing infection where infected areas are present. It reduces the danger of general peritonitis by the use of gauze packing. It renders injuries to the bowel, ureters, important blood-vessels, etc., less likely. It minimizes the danger of hemorrhage. It aids generally by the facility offered for inspection. Through the abdominal incision the surgeon is able to open the belly to the proximal side of the infected area, when, by the proper disposition of sterile gauze sheets, practically all risk of peritoneal contamination is done away with. It enables the surgeon to operate with a very few instruments. Radical operations per vaginam are, with few exceptions, the author thinks, to be discountenanced, for several good and sound reasons: (1) The limited area for manipulation. (2) The impossibility of inspection without destruction and removal of the uterus, which should not be removed except for good and sufficient disease of that organ itself. (3) The marked increased liability to hemorrhage, both primary and secondary. (4) Increased danger of injuring ureters, bowel, bladder, and large blood-vessels. (5) Danger of doing incomplete surgery. (6) Inability to repair satisfactorily injuries to bowel or bladder, etc. (7) Inability to deal safely with an inflammatory mass which involves the vermiform appendix.

Fibroids in the Non-Pregnant Uterus.—A paper on this subject was read by Dr. E. F. Fish of Milwaukee, Wisconsin. The author discussed the advisability of operating in all cases of fibroids of the uterus as soon as discovered and leaves it

an open question. He emphasizes the necessity of radical interference whenever the tumor or tumors are productive of symptoms—pain, hemorrhage, pressure, constitutional impairment—unless there be existing disease, such as nephritis, diabetes, tuberculosis, etc. Of radical treatment, he thinks that myomectomy is the operation of choice, whether subserous, interstitial, or subcutaneous, if it is single and can be enucleated without loss of tissue and the cavity closed and covered with peritoneum. Where several tumors exist, the judgment of the operator comes into play. Many nodules mean many foci, and the author opposes myomectomy on the ground that some of these may not be discovered and later develop and demand another operation. He thinks, too, that under such circumstances the condition is a general one extending to the tubes and ovaries, and this condition might, and likely would, call for future operation. The vaginal route is favored for small tumors, the abdominal for large ones. Hysterectomy is favored when the tumor involves so much uterine tissue that a proper closing of the tumor cavity is not possible, when the organ is studded with small tumors or nodes, when there is coexisting pelvic disease, when the growth is degenerating, when there are adhesions, when the tubes and ovaries are involved to such an extent that they must be sacrificed, when the disease is no longer local, when the change of life has occurred. He favors supravaginal amputation, leaving the cervix when sound, and panhysterectomy when the cervix is lacerated or diseased. He leaves the ovaries if sound, or if only one is sound he leaves that, or if only part of one he leaves that. He believes in ignipuncture for small pea-like cysts and leaves the ovary. He is convinced that it modifies the nervous symptoms which usually follow complete removal. Palliative treatment is discussed, the author paying most attention to curettage and electricity, and he briefly touches on salpingo-oophorectomy, ligation of the uterine artery, organopathy, medical treatment, and natural cures. He concludes that myomectomy is the operation of choice, (1) when the tumor is pedunculated; (2) when single, whether subserous, interstitial, or subcutaneous, and can be enucleated without loss of uterine tissue, and the tumor cavity closed and covered with peritoneum; (3) when the desire for an heir outweighs all other considerations. Hysterectomy indicated (1) when the tumor involves so much of the uterus that a cavity too large to be properly closed and covered with peritoneum would follow its removal; (2) where several tumors exist, especially little nodules; (3) when the adnexa are diseased to such an extent that they must be sacrificed; (4) when the disease ceases to be local; (5) when hemorrhage, pressure, or pain is a persistent symptom; (6) whenever malignancy is suspected or the tumor is of rapid growth; (7) after the change of life. Palliative treatment is indicated when the patient is much reduced from loss of blood, as a prelude to rational cure; when the existence of chronic nephritis, diabetes, tuberculosis, or other constitutional disease forbids radical cure; and when the patient is past forty years of age, the tumor small, the main annoyance hemorrhage, and she is desirous of awaiting the effect of the menopause.

Acute Senile Endometritis.—Dr. L. H. Dunning of Indianapolis, Indiana, read a paper with this title, it being the second written by him upon this subject, in which he reaffirms his belief that it is a distinct lesion that has not heretofore been adequately described. Since his previous paper he has encountered three more cases, two of which were attended by sanguineo-purulent discharges from the uterus and one in which there was a large pelvic abscess. The inflammation tends to spread beyond the endometrium into the Fallopian tubes, ovaries and pelvic peritoneum, resulting in much suffering and ill health and not infrequently leading to so serious involvement of these structures as to demand operative procedures, such as extirpation of the uterus and appendages, or vaginal incision and drainage of a pelvic abscess. The chief cause of the lesion is infection. It is not definitely self-limited, but tends to become chronic and to lead to marked degenerative changes within the uterus. The treatment recommended is, in cases where the appendages are not involved, dilatation, curettage, the application of a mild caustic and prolonged drainage. When the uterine appendages are involved in the inflammatory process, extirpation of the uterus and appendages is advocated.

Tubo-Ovarian Abscess.—A paper on this subject was read by Dr. Edwin Ricketts of Cincinnati, Ohio. Tubo-ovarian abscess is frequently caused by the proximity of the ovary to an infected Fallopian tube. The disease may be complicated by normal or ectopic pregnancy, intestinal, vaginal or vesical fistulæ, and by appendicitis. In the dormant stage the author operates by the abdominal route; in the acute stage he explores by the abdominal route, and then decides between completing the operation in one or two sittings. Following abortion or delivery at full term, vaginal drainage in his opinion often puts the patient in better shape for an abdominal section later on.

Malignant Disease of the Pelvic Organs.—This paper was read by Augustus P. Clarke of Cambridge, Massachusetts. Cancer may have its starting point in a lacerated cervix uteri; but its seat of development is usually in the epithelium. Its occurrence not infrequently takes place after the patient has become a multipara and before she has become of advanced age. The exposure of the mucous membrane to continued or repeated irritation hastens its onset. Cancer of the uterine body has had its origin from endometritis and from its allied conditions. The disease may be induced or intensified by inflammation of the utricular glands

of the uterus and by the effects of external pressure. A sarcomatous condition may result from the same cause. Cancer of the broad ligament, as also that of the ureter, has been observed as the result of extension from the uterine cervix. The meatus urinarius has been noticed as an original seat of cancer. In such cases vesical and urethral disturbances have been known to antedate the appearance of the malignant change. Cancer of the ovary, or of other portions of the adnexa, may occur as secondary to a primary point of invasion. The route of transmission is usually along the course of neighboring lymphatics, or along the epithelial cells of the ducts of such open channels of communication. The fact that cancer cells may so readily invade the epithelium of newly-formed growths containing endothelium shows the importance of taking measures for their early removal before degenerative changes have extensively occurred. The morbid development undoubtedly arises at times by abnormal proliferation of the epithelium from its basic point of origin to the deeper structures within. The majority of cases of cancer occurring in the bladder are secondary to involvement of the cervical portion of the uterus. The cases which call for special consideration are those of the villous type. Curettement and the employment of the galvanocautery afford the best means of relief. In those cases of rectal cancer in which the sphincter ani is not invaded, excision of a portion of the rectum and the removal of the coccyx and the lower section of the sacrum can sometimes be advantageously done. The use of the Murphy button in such cases is of service. The only effectual radical method of treatment is by excision. Partial removal of the uterus on account of extensive invasion by malignant disease will not suffice. The fact that uterine or pelvic fibroids and fibromyomata may take on malignant transformation is becoming more and more recognized. The necessity of watching closely for changes that may be assured becomes obvious. Both round and spindle-celled sarcoma may originate in benign fibroids. The total excision of such neoplasms in their earliest stages will afford the most satisfactory results.

Difficult and Obscure Pus Cases.—Walter B. Chase of Brooklyn read a paper on this subject. The author first considers the etiology of these cases, classing gonorrhea as the most frequent cause, closely followed by miscarriage and labor at full term, these usually following some infection from without. Among the causes from within are considered those following the rupture of an ectopic tubal pregnancy, hematoma, malignant or tuberculous disease, and others less frequent in occurrence.

The question of time should be considered in the diagnosis, but the great mainstay is thorough and systematic bimanual and rectal examination. The author calls attention to the fact that fluctuation may be due to cystic growths, recent hematomata, amyloid degeneration, etc., as well as pus. Pain and fever, or their absence, go far to clear up diagnosis in many a case, but the fever due to malignancy must not be confused with that due to septic causes. Appendicitis and pus tubes may cause difficulty in differentiation. The rule that pus in the pelvic cavity must be evacuated is general, although not universal. The manner and route of its evacuation are thoroughly discussed. Drainage is next considered, the author taking up the direction and the material, usually preferring plain or iodoform gauze, and at the same time considering irrigation, for which he generally uses normal salt solution. Multiple abscesses are considered next with their management. The serious cases in which pus exists free in the pelvic cavity are taken up, and among other things he states that sentiment should be allowed no weight in their treatment. Another embarrassment to the operator is the failure of the public to discriminate as to the cause of fatality, in many of which cases the operator has nothing to do with the mortality. In closing, he cites several pertinent cases, in one of which two abscesses were caused by the escape of the bacillus coli communis, evidently from a denuded spot on the serous covering of the bowel.

HARVARD MEDICAL SOCIETY.

Stated Meeting, Held April 28, 1900.

The President, John B. Walker, M.D., in the Chair.

Cholecystectomy for Gall-Stones.—Dr. Charles L. Gibson read a paper on this subject. He said that it is not very long ago since the first successful removal of the gall-bladder for cholelitheasis was reported. The operation appeared to be too radical and it was long before even simpler operations upon the gall-bladder seemed justifiable to the surgical mind. The original habitat of cholecystectomy was Germany and it is only there that the operation has been tried to any serious extent. English surgeons have not taken to it and the French have practised it very little. Here in America we have been almost as conservative as the English surgeons. The records of the New York Surgical Society contain but two cases of extirpation of the gall-bladder. There is no doubt, however, that this operation has a great future before it and a wide sphere of usefulness. Time was when surgeons considered it sufficient to incise and drain the abscess that occurred in appendicitis. It was years before the thought of the radical removal of the appendix for all of these cases finally asserted itself. The same thing will undoubtedly take place with regard to operations upon the gall-bladder. Cholecystotomy will in many selected cases undoubtedly be replaced by cholecystectomy. Dr. Gibson has had two cases differing very widely in the symptoms they presented and

in the condition which existed at the time of the operation for which he has deemed it advisable to do cholecystectomy.

Cholithiasis Simulating Appendicitis. — Dr. Gibson's first case was a young woman of twenty-two on whom double oophorectomy had been done some time before. She was suddenly attacked with pain in the right side and back accompanied by a chill and a temperature that ran up to 103° F. and a pulse of 120. The right half of the abdomen was extremely tender and the muscles rigid and board-like. The seat of the pain was not very well defined and seemed to occupy rather the lower than the upper half of the abdomen. The diagnosis of the case at first was appendicitis. The very short history, however, seemed to contradict this unless it were an appendicial inflammation of a very virulent character. There was no history that would point to the presence of gall-stones, although the patient thought that she had at times been bilious. The incision in the abdominal wall was made midway between the cecum and the gall-bladder. A large, elongated gall-bladder sausage-like in appearance, parallel to, but not projecting below, the liver was found. It was full of biliary calculi. By gentle, blunt dissection it was easy to free it from all adhesions and its removal was decided upon. The duct was closed by a suture and the lower angle of the wound in the abdominal wall was left open for drainage. At the end of twenty-four hours the temperature reached 105° F. as the result of reaction after the operation. It was feared that some leakage of bile into the abdominal cavity had occurred. The temperature came down, however, and did not rise again. Drainage was removed on the third day and firm union took place within the month. No further complications were noted.

Fatal Capillary Oozing.—The second case was a patient who for five months had suffered a great deal with pain in the region of the liver. This was the characteristic sharp, lancinating pain of biliary calculus. Marked jaundice developed and clay-colored stools were noted with the symptoms of disturbed nutrition which signify an occlusion of the bile-duct. She lost sixty pounds in weight. The jaundice became of a deep yellow and ecchymoses and petechiæ hemorrhagicæ occurred in the skin and mucous membrane. A six-inch incision parallel to the edge of the ribs was made and the gall-bladder was found hard and contracted to the size of a crab-apple. Drainage was extremely difficult because of the extent of the adhesions and the depth to which it had to be carried from the skin surface. The patient did not rally well. After the dressing there was a good deal of oozing and some bile was also discharged. The patient's general weakness increased very much and became so marked that it was feared that internal bleeding was causing exhaustion. On the second day the wound was reopened and an enormous hematoma was found and was turned out. Despite packing, however, the oozing continued. No large vessels were bleeding, but there was the capillary oozing so characteristic of advanced icterus. Death took place one hour after the reopening of the wound for the purpose of controlling the hemorrhage.

Conclusions.—The first case shows that the radical operation of removing the gall-bladder obviates the use of long-continued drainage and also the possibility of a persistent biliary fistula. That this second danger is no unfounded dread, any one who knows the number of persistent biliary fistulæ that exist will understand. The second case shows the utter inadvisability of allowing cases of biliary trouble to go on for long periods, and on the other hand emphasizes the inadvisability of operating on weakened patients in whom icterus has existed for a long time. The radical removal of the gall-bladder restores the liver secretion to the intestine and reestablishes the physiology of intestinal digestion. This shortens very much the convalescence of these cases. As a rule the gall-bladder is easier to get out than a pus-tube. Cholecystectomy assures the radical cure. In this respect it is much more certain than cholecystotomy. If biliary symptoms were not allowed to continue for long periods of time before being referred to the surgeon the formation of adhesions and the spread of the inflammatory condition would be greatly lessened. This would facilitate the operation of cholecystectomy very much. The removal of the gall-bladder is not the operation of choice for every case. It is not meant to be adopted as a routine measure. It is for selected cases. Cholecystotomy is followed by recurrence in about six per cent. of all cases in which it is performed. Kehr, whose large experience in biliary surgery makes his opinion of great value, does not consider cholecystotomy in any sense a radical operation. It requires more skill to do a cholecystectomy, but the greater the experience in biliary surgery the more often is it done, because of the freedom from relapse guaranteed. The operation need not necessarily be a long one in uncomplicated cases. It has been done in less than fifteen minutes from the time of the incision until the suturing is done. The mortality of the operation is higher than that of cholecystotomy, but is not forbidding. It should be carefully ascertained that all the ducts are free before the operation is undertaken. It has been objected that with the gall-bladder removed if trouble should ever occur in the bile-ducts afterward there would be no guide to their position. The objection, however, seems far-fetched.

Comparative Anatomy of Gall-Bladder.—It has been objected that the operation of cholecystectomy removes an organ that has a certain rôle of usefulness in the body. As a matter of fact, however, the gall-bladder is of very little value. The comparative anatomy of the gall-bladder makes it appear almost a joke to insist on the usefulness of this organ. Some animals possess it, some not, and there seems no special difference in the digestive functions of the two classes.

That the gall-bladder acts as a reservoir for bile secreted during the intervals of digestion is a fairy story that has been exploded for a long time. Normally it holds less than an ounce while the system secretes and consumes from twenty to thirty ounces a day. The storage capacity of a reservoir which holds less than an ounce would be totally inadequate.

Danger of Malignancy.—There is no doubt now that chronic irritation may produce malignancy. It is worth while, therefore, for purposes of prophylaxis for cancer to remove a gall-bladder that has been suffering for a long time from chronic irritation because of the presence of biliary calculi. Cancer of the gall-bladder is not an infrequent condition. Where no gall-stones have existed, however, it is extremely rare. The removal of a calculous gall-bladder is now recognized as a most fruitful cancer prophylactic. Ideal cholecystotomy, that is, an incision made into the gall-bladder followed by the removal of gall-stones and then by immediate suture of gall-bladder and of the abdominal incision, would seem to be a most desirable operation. It is not, however, feasible in most cases. The presence of stones in the gall-bladder has practically always led to infection. The contents of the gall-bladder when calculi exist are never sterile. Therefore closing up a gall-bladder after the removal of gall-stones is like closing up an abscess after the fluid purulent contents have been removed. Ideal cholecystotomy has been accomplished successfully but only under very exceptional circumstances. It always has a large element of danger in it and in most cases the incision will have to be opened again and the gall-bladder and its neighborhood thoroughly drained.

Cholecystotomy and Drainage.—In the discussion Dr. Howard Lilienthal said that chloecystotomy need not necessarily be followed by long drainage. This is often presented as an objection to the operation, but it can be avoided by proper technic. If the cut edges of the gall-bladder are inverted so that the peritoneal surfaces come together and a drainage-tube inserted at one angle of the wound, the opening will close usually in twenty-four hours. This method was discovered by a western surgeon and has been used in a number of cases by Dr. McBurney with marked success. As an alternative to cholecystotomy it must not be forgotten that cholecystenterostomy can be employed. Modern surgery is, however, advancing in the line of radical rather than palliative operations. Cholecystectomy is undoubtedly one of the radical operations that will commend itself to surgeons in the near future. It must be borne in mind that an absolute contraindication to the performance of cholecystectomy is the presence of an obstruction in the common bile-duct. That the common bile-duct is free must be definitely ascertained before any attempt is made to remove the gall-bladder. The objection offered, that after the removal of the gall-bladder it would be difficult to locate the common biliary duct, should further trouble occur there, seems trivial. Anatomical relations make it possible to find the duct, although the difficulty of doing so may be considerably increased with the gall-bladder absent.

Complete Operation.—Dr. Brewer said that surgeons are abandoning incomplete for complete operations in many lines of surgical work. This is typically true of appendicitis. It is easy to see that the chronic inflammatory condition of the gall-bladder is an analogous condition to chronic inflammation of the appendix. Both of them occur in hollow organs in connection with the intestinal canal, both are liable to infection and neither show any marked tendency to spontaneous cure. Appendectomy has come to stay; cholecystectomy has surely a bright future. In old cases it is not devoid of danger. Adhesions may make the removal of the gall-bladder a very serious operation. It will always have a larger mortality than cholecystotomy, but the advantage that it practically guarantees against recurrence seems to be enough to offset this objection.

Absence of Gall-Bladder.—Dr. Brewer has seen two cases, one of them in the dissecting-room, in which the gall-bladder was absent. In one case the patient was supposed to be suffering from cholecystitis. An incision was made over the usual location of the gall-bladder, but none could be found. For an hour careful search was made without success. As complete absence of the gall-bladder is a very infrequent anomaly, it was supposed that the gall-bladder in this case was buried in the hepatic tissues and so escaped discovery. At the autopsy, however, it was found that no gall-bladder was present. What had been supposed to be the cystic duct was really a branch of the hepatic duct entering another portion of the liver. The symptoms had been occasioned by inflammatory adhesions surrounding the biliary duct. These adhesions were due to a perforating ulcer of the stomach on the lesser curvature not far from the pylorus.

Dr. Foote said that operations for pathological conditions of the biliary tracts are often very complicated. Seldom do two cases occur that present similar conditions. There is much more difference between successive cases than is encountered in appendectomy. The anatomy of biliary region is much more complicated than that of the cecum and the appendix. It is extremely inadvisable to allow biliary conditions to recur and grow worse with each recurrence. Adhesions form, the normal anatomy and its landmarks become obliterated, until finally operation becomes a very difficult matter. Dr. McCosh says that the great bother with operations upon the gall-passages at the present moment is that medical men refuse to counsel operation until the patient has suffered for months, is so weakened by jaundice that a severe blood dyscrasia sets in and then the patient dies of post-operative capillary hemorrhage in spite of the most careful precautions on the part of the surgeon.

Dr. John B. Walker said that undoubtedly the

greatest danger in operations upon the biliary tract where jaundice has existed for some time is uncontrollable capillary hemorrhage. He recently saw a death from this cause in a man of sixty where nothing would stop the bleeding. Operations upon the gall-passages must not be looked upon as a last resort, but rather as something to be thought of as soon as pronounced symptoms of the presence of a calculus or some other pathological condition of the biliary tract become clear. There is very little hope of spontaneous recovery once an undoubted attack has taken place. Recurrent attacks lead to the formation of dense adhesions that greatly obscure the field of operation.

A Surgical Operation.—Dr. Brewer said that in operating in private houses he has often found it difficult to be assured of having at hand the dressings and bandages needed for various operations. Because of this he has a package made up, all of the material in which can be thoroughly sterilized beforehand. This can be carried to the place of operation when needed and the surgeon will always be sure of having just what he wants. Besides gauze, this package contains materials for rubber drains such as Morris uses, a rubber head-apron, to surround the field of operation, cover the hair and the ether apparatus in operations upon the head, and a round rubber band, about two feet long and over a half inch in diameter, which can be used to compress the blood-vessels in the extremities. Dr. Brewer also presented some gloves which had recently been prepared for him. They are of good, thin rubber, durable, not too slippery when wet, stand washing well and may be put on easily.

Dr. Howard Lilienthal considers that a mouth-mask of gauze is of more importance than the use of gloves for the hands. The hands may be cleansed with reasonable thoroughness. It is impossible, however, to prevent small particles of saliva from the always infected mouth from being carried out into the air above an operation wound, especially if the operator talks during the operation. Experiment has shown that even when people are most careful, impalpable and invisible particles of saliva from the mouth find their way out during the talk. It is a common experience with all of us that there are people, and some of them are surgeons, from whose mouth the particles that proceed cannot exactly be said to be impalpable and invisible. Three or four thicknesses of gauze over the mouth are sufficient to prevent this. It has often been shown that conversation of any kind carried on over a culture medium is followed by the growth of micro-organisms. Expiration through the nose has not this effect. The apparatus in the nose which protects us from carrying bacteria into the lungs also prevents us to a large extent from expelling bacteria with the expired breath. While the operator may remove his operating-gloves for purposes of palpation, the mouth-mask should not be removed and conversation should be limited as much as possible. Needless to say a turban should be worn over the hair during operation. There is no doubt that results are much better in the hands of those who carry out carefully these protective precautions. Besides, the surgeon's conscience is better should anything untoward happen, since he has the assurance that every possible precaution was taken.

Dr. Walker said that the results in operations for hernia, for instance, are much better since the introduction of gloves. This is not only the common impression among surgeons who use gloves, but it is an actual deduction from statistics. Not only is there a distinct decrease in the mortality, but the morbidity has been very much lowered. At Johns Hopkins Hospital, for example, in about ten per cent. of the cases before the introduction of gloves some morbid symptoms developed that pointed to an infection with pus micro-organisms, though usually not of a serious nature. In recent cases, however, there have been such symptoms in only about one per cent. It seems evident, therefore, that the mouth-mask while adding a good deal to the inconvenience of the operator will not improve his results very much. Gloves have, however, proved beyond all doubt their right to a place in the domain of surgery. They have surely come to stay.

NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting, Held April 23, 1900.

The Vice-President, J. Clifton Edgar, M.D. in the Chair.

Tetanus, Its Nature.—Dr. Alexis V. Moschcowitz said the scientific study of tetanus began with Nicolaier's discovery of the bacillus of tetanus in 1884. Kitasato obtained the bacillus tetanus in pure culture in 1891. Before that time the most varied theories existed with regard to the causes of tetanus. Some of the adjectives which still remain as descriptive terms for the various forms of tetanus are derived from these theories. Rheumatic tetanus of course is a misnomer and idiopathic tetanus only has an existence in the minds of those who, having sought too perfunctorily for the site of inoculation of the disease and not found it, consider therefore that somehow it originates of itself. Such slight wounds as that of a hypodermic needle or the sting of a bee are sufficient to convey the disease. There seems to be no reason to doubt that inoculation may sometimes take place through mucous membrane, especially where excoriations exist. Not only the mucous membrane of the gastrointestinal tract but also that of the respiratory tract is liable to be the avenue of entrance. The tetanus bacillus multiplies only at the point of infection. It does not find it way by metastases through the system. During its growth at the point of inoculation toxins of an intensely virulent character are produced

and their absorption causes the symptoms of tetanus. The division of tetanus into forms is justified by the train of symptoms that always occur in them. Cephalic tetanus from a wound on the head always develops its symptoms in the region supplied by the facial nerve on the same side as the wound through which inoculation took place. Puerperal tetanus is always due to an inoculation in the genital region. Widal and Chantemesse have obtained the bacillus tetanus in pure culture from the vagina. Curiously enough the first symptoms of the disease are noticed in the neck and face muscles and not in the abdomen. Trismus is usually the preliminary sign. Tetanus neonatorum is always due to an infection of the umbilicus of the newly-born with the tetanus bacillus. The first symptom is the failure of the child to nurse. As in the case of the puerperal woman it is trismus that opens the scene.

Pathology.—The pathology of the disease, notwithstanding all the investigations that have been made on the subject, remains as yet indefinite. Many peripheral and central nerve-changes have been described in addition to pathological appearances in the sympathetic, but none of them are sufficiently uniform to be set down as the absolute characteristic of the disease. The most uniform pathological condition noted is a hyperemia of the nerve-centers. An important fact with regard to the central nervous system is that the normal brain and cord substance is somewhat antitoxic, that is, is capable of neutralizing to a certain extent tetanus toxins. On the other hand it is in the cerebrospinal fluid that the most virulent toxin of the disease is found. Stintzing showed that the cerebrospinal fluid of patients attacked with tetanus when injected into mice caused attacks of the disease. The results obtained were not, however, absolutely uniform. There was a very early and a delayed effect from the injection. In some animals the disease developed in from two to three days, while in others it was later than the tenth day and even as late as the twenty-sixth day. The toxins formed at the point of inoculation seem to find their way into the central nervous system through the perineurium of the nerves. Its main point of attack in the spinal cord is the large cells of the anterior horns.

Prognosis.—This depends upon two things. First, the length of incubation of the disease, and, secondly, upon the acuity of the affection. The mortality of the disease is variously reported. As high as 96 per cent. is claimed by one observer. The average mortality twenty years ago was about 60 per cent. During the last ten years the average mortality has been 40 per cent., although one Italian physician claims that only 20 per cent. of his cases died. Dr. Moschcowitz has collected the statistics of 290 cases treated with antitoxin by the subcutaneous method. Of these 117 died. During the past year or two, since the publication of Roux and Borrell's observations upon the effect of antitoxin injected directly into the brain of tetanized animals, a number of cases of tetanus in the human being have been treated by intracerebral injections. Dr. Moschcowitz has been able to collect 48 of these. All of them were of the very severest type and were practically hopeless when the injections were made. A little over 50 per cent. of them recovered.

Treatment.—The indications for treatment may be ranged under the following heads: (1) Destroy the bacteria present and prevent the further absorption of toxins. (2) Eliminate as far as possible all toxins that have been absorbed. (3) Failing to eliminate, neutralize the toxins already present in the circulation. (4) Anticipate the symptoms of the disease and its development by immunizing patients before the disease develops. (5) Overcome the symptoms of the disease by the administration of remedies that promise to have an opposite effect upon the organism.

In answer to the first indication the wound of entrance should be promptly enlarged; any foreign bodies or dirt that may be therein should be thoroughly removed so as to get rid of all the infectious material. The most fertile source of tetanus in our large cities is the toy pistol. It is often surprising to find that doctors have permitted portions of the wad of a blank cartridge to remain in the wound for days. Thorough disinfection of the tissues should then be accomplished. For this bichloride solution, 1-1000, or ½ per cent. hydrochloric-acid solution, ½ per cent., or peroxide of hydrogen, or a reasonable strong solution of silver nitrate should be used.

For purposes of elimination it seems worth while to produce prompt catharsis and diuresis. Diaphoresis will also aid in eliminating the toxin, but there is usually no necessity for artificially aiding this function as it is excited by the presence of the toxins of the disease. In the same line of elimination venesection may be employed. As much normal salt solution should be introduced beneath the skin as there is blood removed.

The third indication, the neutralization of the toxins, is accomplished by antitoxic treatment. Unfortunately, before symptoms of tetanus announce themselves, the toxins of the disease have become more or less permanently fixed in the cells of the central nervous system where the antitoxin is unable to affect it. The antitoxin of tetanus is not merely a chemical neutralizer of the toxin, that is, it does not change the toxin to an innocuous substance when mixed with it outside of the body, but is able to produce its effect only when brought into play by the cellular energy of the body tissues.

Immunity can be produced if the antitoxin is given before symptoms of tetanus declare themselves. Unfortunately, we cannot be sure of the cases that are going to develop tetanus or we

would be able to prevent all cases of the disease. When symptoms develop in a tetanic patient, this is not the beginning of the tetanus, but, as has been well said, is the beginning of death from tetanus. The antitoxin may be given as a prophylactic and it has been used as such in a number of reported cases. This is in fact the most promising field for the use of antitoxin subcutaneously. At the Gebaer Anstalt at Prague an epidemic of puerperal tetanus defied all efforts toward its eradication. It was cut short by the prophylactic administration of tetanus antitoxin to every patient who entered the institution. Since then it has become a routine practice in some institutions where tetanus constituted a certain amount of danger for puerperal patients. The prophylactic injection of tetanus antitoxin has also given excellent satisfaction in veterinary practice.. The subcutaneous injection of antitoxin has undoubtedly lessened the death-rate from the disease. For reasons obvious from what we have said with regard to the fixation of the toxins by the cells of the central nervous system, it often comes too late to do any good. In order to offset this Roux and Borrell suggested as the result of experiments on animals the intracerebral injection of antitoxin. This has been used in a sufficient number of cases now to make it clear that it is of some service, although a definite idea of its value cannot perhaps as yet be given.

As to symptomatic treatment of the convulsions chloral, the bromides, opium, and hyoscyamus should be given. As to other methods of treatment recently prominent, subcutaneous injections of brain substance seem not unworthy of mention. As has been said the cells of the central nervous system seem to contain a certain amount of the substance that is antitoxic for tetanus toxins. It is because of this that the brain injections have been employed. Bacelli's method of injecting large amounts of carbolic acid also seems worthy of mention.

Surgical Prophylaxis and Immunization.—Dr. William H. Park said that the surgical treatment of wounds inflicted on the street should be most careful. When tetanus infection occurs the infected material remains absolutely local and never wanders through the system. If the wounds are thoroughly opened at the beginning the tetanus bacillus will not grow. If even after the development of the first symptoms of tetanus we know where the wound of entrance is, we should open it up to remove the bacilli and prevent the absorption of further toxins. The future of the antitoxic treatment of tetanus seems to lie in its employment for prophylactic purposes. It is very easy to produce immunization. In all the stations for the manufacture of diphtheria antitoxin all of the animals are now immunized against tetanus. Before it became customary to immunize them many were lost from the disease. The New York Board of Health lost six some years ago and then introduced the custom of periodical immunization. Recently because of moving the laboratory this immunization was neglected and a valuable animal was lost shortly afterward. Once the symptoms of tetanus have manifested themselves in an animal the use of antitoxin does not seem to influence the course of the disease.

Immunity for Human Beings.—Tetanus as we see it in the cities is mostly due to injuries inflicted by toy pistols. It would be perfectly justifiable to use antitoxin for prophylactic purposes in these cases. If 2 cc. of tetanus antitoxic serum were injected after every wound inflicted by a blank cartridge tetanus would practically be banished from our cities. The use of the serum subcutaneously does not seem to be of much benefit in severe cases. In milder, chronic cases it does seem to do some good. As a matter of fact, however, when symptoms of tetanus manifest themselves the cells of the central nervous system are ready to die. The use of the serum by intracerebral injection does not seem to add to its value. The operation for the injection is a serious one. Some of the cases reported cured of their tetanus have died later of brain abscess.

Intracerebral Injections.—Dr. Robert Abbe detailed his personal experience with antitoxic serum in the treatment of tetanus On the whole he finds its use of decided benefit. Last summer he saw seven cases of the disease. In five of them, all very bad cases, he used intracerebral injection of tetanus antitoxin. Although all the cases seemed hopeless, three of them recovered. The method of giving the injections employed was that suggested by Kocher of Berne. After a small preliminary incision down to the bone, an ordinary brain drill is employed to pierce the skull. Through this a needle is inserted and the injection given slowly. The needle is pushed on into the lateral ventricle and the injection made into its cavity. If by any chance the point of the needle should penetrate beyond the ventricle the antitoxin comes back over the track of the needle. The point of election for the insertion of the needle is half-way between the outer angle of the orbit and the mid-point of the line over the vertex connecting the external meatuses of the ear. General anesthesia is not necessary for the operation; it can be done under cocaine. The patient is utterly unconscious of pain during the penetration of the needle into the brain substance. There is no heart or respiratory or circulatory disturbance, either at the moment of the operation or later. In one case there was no immediate effect, but slow improvement began shortly after. In the second case there was decided amelioration of the symptoms from the very moment of the injection and convulsions which had been occurring very frequently ceased at once. In two other cases there was amelioration almost at once and a marked effect on the course of the case later on. In a bad case of puerperal tetanus

the patient remained for thirty-six hours without a spasm. When the spasms returned they were slight and subcutaneous injections of the antitoxin were given but without effect. Dr. Abbe believes firmly that intracerebral injections of antitoxic serum have a great future.

The appearance of the wounds through which infection of tetanus takes place is very varied. In a case where the inoculation had taken place in the classical way, by a rusty nail in the foot, the wound had healed so kindly that scarcely any trace of it could be found. Others suppurate and look ugly and when the first symptoms of tetanus begin are apt to have a suspicious look. A gunshot wound of the palm from which tetanus developed had a lardaceous infiltration that seemed to speak for some serious pathogenic agent within the tissues. As in cases of anthrax there is at times an edematous, hard, pork-like condition of the surrounding tissues. It seems well worth while in all cases to thoroughly sterilize wounds where the presence of tetanus may be suspected. Iodine or some other effective antiseptic may be used freely on them.

The prognosis of cases does not always follow the rule that has been set down. Sometimes, although they begin two weeks after the inoculation, they do not run a mild course. Some of the cases that begin mildly have severe exacerbations. It is not an unusual thing to have a sudden relapse more severe than the rest of the disease after a seeming recovery.

Infection Through Frostbite.—Dr. Converse reported a case in which a man lost the terminal phalanges of some of his fingers by gangrene after having had them frozen. When he came to the hospital there was already enough contraction of the facial muscles to produce a typical risus sardonicus. He could move his head laterally, but not anteroposteriorly. He complained that his thorax felt as if in a vise. Amputation of the fingers was done. The spasms continued for some days, but under the use of antitetanic serum subcutaneously gradually abated. Rest and cessation of the convulsion always occurred shortly after an injection of the serum. The convulsions could not be controlled by chloral and bromides, because these drugs gave rise to an intermittency of the heart. In all 720 cc. of serum were given. At first doses of 40 cc. were tried, then 60 and finally 80. The largest dose controlled the convulsive seizures very effectively. Some eruption occurred, especially about the points of injection, and wine-red confluent papules occurred in patches over the body. Desquamation followed. The patient suffered no inconvenience from the eruption, except a slight itching. After the tetanus seemed completely cured, the patient developed symptoms of pyemia and died therefrom. The pyemia seemed to be due to infected serum, the vial which contained it having been allowed by mistake to stand unwrapped and uncorked for some time.

Open Wounds.—Dr. M. Ware said that the tetanus bacillus absolutely refuses to grow in the presence of oxygen. It finds favorable conditions only in the depths of the tissues where free oxygen is excluded. The cardinal prophylactic indication therefore is to lay open all wounds made on the street so thoroughly that they may have free access of air. If this were done in all cases we would have fewer patients suffering from tetanus in the hospitals each year. Air is the very best antiseptic when there is question of tetanus infection. It seems absolutely inadvisable to use the actual cautery or any strongly cauterizing substance where tetanus is suspected. Cauterization makes an eschar which mats the tissues together, occludes the underlying portions, and absolutely shuts off the air. This, instead of hindering the tetanus bacillus, creates favorable conditions for its rapid multiplication and continued growth. Dr. Ware has had under his care during the last few years eleven wounds inflicted by toy pistols. All of them were treated by this open method and none developed tetanus.

Dr. Fisher thinks there is no reason to consider that the nerve-cells are affected by the tetanus toxin. When cells of the central nervous system are affected, the usual result is a palsy; convulsions are never produced. It is irritation of the meninges that gives rise to convulsive symptoms. It is probable therefore that the pathological lesion of tetanus will not be found in the cells, but rather in the meninges.

In closing the discussion Dr. Moschcowitz said he has collected all the cases in which antitetanic serum has been given by intracerebral injection. In only one case did an abscess of the brain develop. In that case the tetanus itself was cured and the abscess developed some eight weeks afterward. At the autopsy the pus of the abscess was found to contain a pure culture of the staphylococcus albus. It is evident that owing to some defect in the surgical technic an infection took place with the fatal results that might be expected. Needless to say the most exact surgical asepsis is required for the intracerebral injections of tetanus antitoxin. Irritation of cerebral tissues and of the meninges is produced by the injection of the fluid. This creates extremely favorable conditions for the multiplication of infectious agents if by any accident they should be introduced. When, owing to the continuation of symptoms, a second intracerebral injection is deemed necessary it is a matter of extreme difficulty to be assured that the granulations through which the injection is made are sterile. Under these circumstances it is well to touch with pure carbolic acid the granulations at the point where the needle is to be introduced in order to destroy any germs that may be present. With proper precautions intracerebral injections are undoubtedly of the greatest service and a distinct advance in the therapeutics of tetanus.

ORIGINAL ARTICLES.

SOME REMARKS ON THE PATHOLOGY AND SURGICAL TREATMENT OF URINARY AND URO-GENITAL TUBERCULOSIS.[1]

BY SAMUEL ALEXANDER, A.M., M.D.,
OF NEW YORK;
PROFESSOR OF GENITO-URINARY DISEASES IN THE CORNELL UNIVERSITY MEDICAL COLLEGE; SURGEON TO BELLEVUE HOSPITAL.

TUBERCULOSIS of the male uro-genital tract does not differ essentially from tuberculosis in other organs of the body, except that it is, perhaps, more frequently complicated by some form of pus infection. The latter may either antedate the invasion of the tissues by the tubercle bacillus or follow this invasion. The pathological changes produced by these pus infections weaken the resistance of the tissues, intensify the symptoms due to the tuberculous process, frequently obscure the diagnosis of the latter, and render treatment in many cases much more difficult.

Tuberculosis of the uro-genital tract is met with clinically in two forms: First, as a secondary infection, the result of tuberculosis in some other portion of the body, as in the lungs, or it may occur as a manifestation of a generally tuberculous infection of the organism; and, secondly, as a seemingly primary infection affecting at the outset one part of the urinary or genital tract more or less extensively, usually chronic in type. It is this latter form of uro-genital tuberculosis that is of most interest to the surgeon.

It seems strange, notwithstanding the frequency with which tuberculosis is met with as an apparently primary lesion of the uro-genital tract, that so little attention has been given to the subject until within very recent years. A review of the literature of this subject, even during the past decade, is certain to be unsatisfactory to the student seeking positive information upon the subject. There is scarcely a single point either in the pathology or treatment of uro-genital tuberculosis which has not been the subject of discussion and yet in regard to which observers do not differ widely. Notwithstanding, however, the very contradictory statements which have been made, I think it will now be generally admitted by those who are entitled to speak with authority that seemingly primary tuberculous infection of the uro-genital tract does occur, and that it does occur with great frequency. I mean by this that tuberculous lesions are met with clinically in the uro-genital tract without tuberculous lesions being found in any other portion of the organism. It is of course possible that in these cases the primary infection may not have been in the uro-genital tract, but may have occurred in some other part of the organism, as, for example, in the pulmonary lymph nodes, the lesion being so slight as to escape detection. But, although this may be admitted, there are many questions which are far from being definitely settled; for example, it is by no means certain as to the manner in which the tubercle bacillus finds entrance into the genito-urinary tract; nor are we certain what is the original seat of the disease in any given case; nor what part of the genito-urinary apparatus is most frequently the seat of primary infection. Any one who is familiar with the clinical aspects of genito-urinary tuberculosis, and who has given any study to recent literature upon this subject, must be convinced that we need more positive knowledge before we shall be able to speak with anything like certainty upon these questions.

This is unfortunate, because of the importance of our having a definite answer to these questions from the standpoint of treatment. I venture to suggest that these questions will not be answered until a closer and more cordial relation has been established between those who are clinical observers and those who work in our pathological laboratories. The results of post-mortem examination and of pathological research alone are unquestionably of great value, but in order to reach sound conclusions from such observations it is necessary that the clinical histories of the cases which form the basis of the investigation should also be known. I believe that the necessity for this cooperation in the study of disease between clinicians and pathologists is now appreciated by the profession, and I have great hopes that owing to this our knowledge of these questions will be greatly increased in the near future.

But while we are waiting for this improvement in our methods of scientific investigation of disease, we cannot lose sight of the fact that we are daily confronted by patients suffering from tuberculosis of the uro-genital tract who demand immediate treatment. The pain and suffering which this form of tuberculosis often causes make it all the more imperative that we should use our utmost endeavors so far as our knowledge goes to relieve it. It is, therefore, necessary at the present time that as practical surgeons we should adopt, if only provisionally, a working hypothesis:

First, tubercle bacilli may be introduced into the urethra and other portions of the urinary apparatus may be involved subsequently by an ascending infection. I say this is possible. Clinical obser-

[1] Read before the New York State Medical Association at the annual meeting, held in New York, October 15, 16, 17, 18, 1900.

vation, however, does not support this view, and I know of no pathological observations to support it. It is certainly true that infection of the anterior portion of the urethra is of very rare occurrence, and when it does occur it is usually the result of the extension of a tuberculous process from the upper urinary tract.

Secondly, I think that it will also be generally admitted that primary tuberculous infection of the uro-genital tract is usually of hemic origin. It is probable that the tubercle bacilli are taken into the organism either through the respiratory or digestive tract, and are then carried by the blood current to some portion of the uro-genital apparatus either directly or indirectly. It seems probable also that tubercle bacilli enter the urinary tract from the blood, most frequently through the kidney. By this I do not mean that the kidney is always the primary seat of genito-urinary tuberculosis—the kidney indeed may frequently escape infection, although the urine coming from it contain the tubercle bacillus. Such urine, containing tubercle bacilli and passing over the mucous membrane of the urinary tract, may cause disease of the bladder and prostate without any infection of the kidney, provided the resistance of these parts has been weakened, as is so frequently the case, by trauma or previous inflammation due to pus infection. This is analogous to the conditions found in ascending and descending pyogenic infections of the uro-genital tract. At the same time clinical observation would lead us to believe that in many if not the majority of cases of urinary tuberculosis the kidney itself sooner or later does not escape infection.

Tuberculous infection of the kidney is usually first met with in the renal pelvis and does not usually begin in the kidney substance. This cannot be stated as a definite rule to which there are no exceptions. I do not believe, however, that all cases of uro-genital tuberculosis are of renal origin. It is certainly possible that the tubercle bacilli may be carried directly by the blood-current to other portions of the urinary or genital tracts, and this undoubtedly does occur, because we find cases in which the disease seems at the start confined to the epididymis or to the prostatic urethra and no evidence, either in the past or in the future history of such cases, makes it necessary for us to insist upon the renal origin of the infection.

Clinically speaking, the most common seat of so-called primary tuberculosis of the uro-genital tract would seem to be in the epididymis. This is always involved before the testicle proper; tuberculosis of the latter I believe only occurs as the direct result of extension of the tuberculous process from the epididymis.

Contrary to the view usually held, my own investigations have led me to believe that, although tuberculous epididymitis may occur alone, it is usually associated with more or less involvement of the prostate or prostatic portion of the urethra. It is impossible, however, to state this as a positive fact, and more study and better observation will be necessary before this can be done.

Again, while it is possible that tuberculosis of the bladder may occur as a primary affection, the clinical data are wanting to confirm such an opinion. It seems almost certain that tuberculosis of the bladder is always secondary to a primary tuberculosis of the kidney, the bladder becoming affected by descending infection, or is secondary to a primary tuberculosis of the lower uro-genital tract, beginning either in the epididymis or in the prostate; the bladder is then affected by an ascending infection.

Tuberculosis of the uro-genital tract is not caused alone by the introduction of the tubercle bacillus into the organism. There must be in addition a weakened cellular resistance of the part affected. The causes of this diminution in resistance in the uro-genital tract are as yet very imperfectly understood.

The object of operative treatment in primary tuberculosis in any portion of the urinary tract is in the first place curative; that is, we seek to remove as thoroughly as possible the entire focus of disease. When this can be done a cure is possible, but possible only in cases where the general tissue resistance of the patient can be increased and maintained. When the disease has advanced too far to permit of its entire removal, an operation may be justifiable for the purpose either of relieving suffering, or of prolonging life, and even in some of these latter cases a cure is possible if the general tissue resistance can be increased and maintained.

I do not think that we recognize sufficiently the fact that the removal of isolated tuberculous foci is not in itself curative. The experience of every hospital surgeon is convincing that, while the immediate effect of operative treatment upon uro-genital tuberculosis is good, the vast majority of these cases are only temporarily relieved and return sooner or later either with an extension of the original disease or with a new focus of infection in some other portion of the body. As this occurs in some cases where apparently the entire focus of disease has been removed, it is probable that the infection of the uro-genital tract was only apparently primary. The results of operation for tuberculosis are much more satisfactory in patients of the better class who are able to procure a suitable environment after operation, so that their general health and powers of resistance may be increased.

The Importance of an Early Diagnosis.—The value of surgical intervention in the treatment of tuberculosis of the uro-genital tract depends upon the direct origin of the infection and upon the seat and extent of the disease. The more circumscribed the lesion, and the more recent the infection, the better chance is there for effecting a radical cure by operation. It follows, therefore, that it is of the utmost importance to make a diagnosis in every case at the earliest possible moment. The methods of diagnosis

have been much improved during the past few years, and it is along this line that the greatest progress has been made in the study of urinary tuberculosis. But our present methods of diagnosis, although a great improvement on those formerly used, are by no means perfect. But, notwithstanding their defects, it is to be greatly regretted that they are not more generally understood.

It cannot be denied by any one, looking fairly at the facts as they now exist, that the diagnosis of tuberculosis in any portion of the urogenital tract is usually not made until the disease is well advanced. For example, it frequently occurs that a patient with a beginning renal tuberculosis will complain of subjective symptoms referable to the bladder, *viz.*, frequent urination, pain and tenesmus at the end of the act, and yet have no vesical or prostatic lesion. The only objective symptom is a slight pyuria with or without hematuria and the latter is often overlooked. Such a case is treated for inflammatory disease of the posterior urethra, or for a cystitis—calculus is often suspected. The patient is subjected to frequent and often unnecessarily severe instrumentation for the purpose of reaching a diagnosis or in the course of treatment, and it is only after repeated examinations have failed to show any lesion of the bladder or of the prostate and after local treatment has failed not only to relieve the patient's condition, but has made him worse, that the possibility of tuberculosis being present begins to be considered. Unfortunately for the patient, as the result of delay and improper treatment, the tuberculous process has spread from the kidney to other portions of the urinary or genital tract, and the favorable opportunity for surgical relief has passed away. The statement may well be emphasized that unnecessary and frequent instrumentation is a fruitful exciting cause for the extension of the tuberculous process in the urinary tract by producing trauma favoring infection, and weakening the resistance.

I believe that it is of the utmost importance in all cases of chronic inflammatory urinary disease, in which the nature of the disease is not perfectly clear, that as a matter of routine practice the urine should be frequently and carefully examined for the presence of tubercle bacilli and that even when tubercle bacilli cannot be found the possibility of tuberculosis should be kept constantly in mind. It has been frequently said that the presence of tubercle bacilli in the urine is difficult to find. This undoubtedly is true in some cases of tuberculosis, especially where but few bacilli are present. I cannot at the present time enter into a detailed description of the best methods for examining urine to determine the presence of this bacillus. I can, however, say as the result of personal experience that the failure to detect tubercle bacilli is more often due to the mode of examination than is usually supposed. The best results can be obtained only when the urine is examined immediately after it has been voided by the patient. The sediment should be collected by centrifuge and slides should be prepared at once. The examination of urine after the specimen has stood for a number of hours and from which the sediment has been collected simply by gravity rarely gives satisfactory results unless a large number of bacilli are present.

In addition to the improvements made in our methods of urinary examination, our ability to make a positive diagnosis has been greatly increased by improvements in the cystoscope and in the facility with which in practised hands this instrument and ureteral catheterism can be employed. In the early stages of tuberculosis direct inspection of the bladder and orifice of the ureter is of great value, and when the conditions are favorable for catheterizing the ureters we can determine the condition of either kidney with great accuracy. Unfortunately, in many cases of advanced disease cystoscopy is impossible, and I am inclined to think that except in skilful hands the practice of cystoscopy and ureteral catheterism does more harm than good.

The result of any operation upon the urogenital tract for tuberculosis is governed by the same rules which we apply to other surgical diseases. The immediate result of any operation will depend upon the general condition of the patient, upon the state of the lungs, and of other organs, upon the age of the patient and the extent and seat of the disease.

Operations upon the Kidney.—Operations for tuberculosis of the kidney may be divided into three classes: (1) Operations in those cases in which the kidney is primarily affected and in which the diagnosis of urinary tuberculosis has been made while the infection is purely bacillary; (2) operations in cases in which the tuberculosis is primarily in the kidney and in which there is a mixed infection, but without tuberculous disease in any other portion of the urinary tract; (3) those cases of advanced tuberculosis of the kidney with secondary tuberculosis of other portions of the urinary tract. I believe that in all cases of tuberculosis of the kidney in which an operation is not absolutely contraindicated by the general condition of the patient, surgical interference is not only justifiable, but is imperatively demanded. The results of operation, however, will vary within very wide limits, and at the present time it is impossible to generalize in regard to the prognosis of any of the three classes of cases mentioned above. As a general rule when operation upon the kidney for tuberculosis is indicated the choice should be given to nephrectomy.[1] Recent statistics show that the immediate mortality of nephrectomy and nephrotomy is about equal, but the remote results are greatly in favor of nephrectomy. We find that 61.71 per cent. of cases died during the first year after nephrotomy, while only 12.54 per cent. died during the first year after nephrectomy. Of 63 cases operated upon by nephrotomy 39 died during the first year, and of the 24 that survived all had permanent fistulæ. Of 335

cases operated upon by nephrectomy 42 died during the first year by a spread of the tuberculous process to other organs. Of the 293 which survived the operation 33 were living at the end of the first year, 41 lived three years, 4 lived five years, 7 lived six years, and 2 lived eight years. A very small proportion of these cases suffered from fistula, namely 7 in 105 operations. It would seem, therefore, that nephrectomy should always be the operation of choice where only one kidney is affected, and I believe that the operation is frequently indicated even when the other kidney is the seat of beginning tuberculous infection, if the patient be put in surgical condition. The question has been frequently discussed as to the necessity of removing the ureter in cases of nephrectomy performed for tuberculosis. To do this increases the risk of the operation and frequently, I believe, subjects the patient to unnecessary risk.

In early cases of renal tuberculosis the upper part of the ureter is alone affected. In advanced cases in which the entire ureter is involved the operation upon the kidney is only palliative; and to remove the kidney simply increases the risk of the operation without doing any permanent good.

Tuberculosis of the Genital Tract.—Primary tuberculous infection of the genital tract may begin in the epididymis, or in the prostate, or possibly in the seminal vesicles; the primary involvement of the latter is very doubtful. The genital tract may also be involved secondarily as the result of tuberculosis of some portion of the urinary tract. Tuberculosis as a primary infection of the genital tract attacks most frequently the epididymis, but I believe that the prostate is more frequently the seat of tuberculosis than is usually supposed. Tuberculosis of the seminal vesicle is, I believe, nearly always secondary to tuberculosis of the epididymis or of the prostate. The spermatic ducts, or vasa deferentia, are never primarily infected by the tubercle bacilli. In these canals the disease is always secondary either to tuberculosis of the epididymis or of the prostate. If these statements are true it is apparent how important is an early and accurate diagnosis of the exact seat of the lesion in determining the extent of an operation.

Cases of genital tuberculosis may be generally classified into three groups: First, when the epididymis is the seat of primary disease and when the disease is limited to this part; second, when the epididymis is involved as the result of a descending infection from the prostate, but without involvement of the seminal canal; third, when the testis proper, as well as the epididymis, is involved, and in such cases the seminal canal is always more or less the seat of tuberculous diseases.

It would be impossible at the present time for me to discuss at all fully this question of operations upon the genital tract for it is the subject of active discussion among all those interested in genito-urinary surgery. Opinions of the most competent of observers differ so widely upon this subject that I am forced to give only my own opinion, which is based upon a large clinical experience. The principal questions at issue may be formulated as follows: (1) Is castration indicated in every tuberculous condition of the epididymis, or can we by more conservative methods accomplish the same results? (2) When the epididymis or testicle alone is involved is it necessary for us to remove the seminal canals and seminal vesicles and portions of the prostate, even if these latter do not appear at the time to be the seat of disease? At present I am very strongly of the opinion that when the epididymis is the seat of primary disease, and even in cases where there is some involvement of the prostate, if the testicle itself be healthy a conservative operation will give as good results as castration. Excision of the epididymis, together with as much of the seminal canal as seems to be diseased is, I believe, the operation of choice in early cases. It is possible by opening the inguinal canal to remove the seminal canal nearly as far as its junction with the duct of the seminal vesicle. And I believe that when the epididymis or a testicle has to be removed for tuberculosis it is best to remove as much of the seminal duct as can be done through this incision. When the testicle proper is the seat of a tuberculous process conservative measures are useless and castration with the removal at the same time of the seminal canal is the only operation to be considered. In such cases the prognosis is usually bad as to ultimate cure, and the operation can only be considered as a palliative measure. The value of more extensive operations upon the genital tract, which aim not only to remove the diseased testes and cord, but also the seminal vesicles and more or less of the prostate, are now under consideration. I think that my own is in accord with those who have had much experience with these operations. They are difficult to perform and the results which follow such surgical interference have been far from satisfactory.

Tuberculosis of the Prostate.—Primary tuberculosis of the prostate has been denied by many very competent observers. The statement by Sir Henry Thompson that the prostate was never the seat of primary tuberculosis has been accepted and, I believe, still influences the thought of the present time. I am convinced that primary tuberculosis of the prostate does occur and is far from infrequent. It is difficult to diagnose, and, as a rule, the tuberculous process has extended from the prostate to other portions of the genital or urinary tract before the diagnosis is made. It is frequently possible by pressure upon the prostate with the finger introduced into the rectum to obtain the secretion from the prostatic follicles, which, upon examination, will be found to contain tubercle bacilli when repeated examinations of the urine have been negative. Except in cases of isolated tuberculous

nodules in the prostate, or in cases in which such nodules have broken down and have resulted in so-called tuberculous prostatic abscesses, there is little that we can do with certainty for the disease in this organ. I am strongly of the opinion that in a large number of cases of slow developing abscess of the prostate the cause of the condition when carefully sought for will be found to be tuberculosis. In such cases I believe that the proper course to pursue is to remove as completely as possible the diseased portion of the prostate, and I am sure that in many cases this can be done with great benefit to the patient.

Tuberculosis of the Bladder.—As I have already stated tuberculosis of the bladder is, I believe, always secondary either to tuberculosis of the kidney or of the lower uro-genital tract. It is, of course, possible that the bladder may be primarily infected, but clinical experience and the results of post-mortem examinations show that this rarely occurs. The surgical treatment, therefore, of bladder tuberculosis can never be curative and must be regarded only as a palliative measure unless the original seat of the tuberculous infection can also be removed. Local treatment of tuberculosis of the bladder is, I believe, absolutely valueless. When the bladder is involved by a tuberculous process, and the condition is complicated by some form of pus infection, local treatment may give some relief by controlling the latter, but each treatment has no effect upon the progress of the tuberculosis. There are few conditions met with by the surgeon in which he can do so little as he can to relieve the symptoms resulting from tuberculous infection of the bladder. It may be possible at times by opening the bladder to apply local treatment more effectually and subsequently, by draining of the viscus, to relieve suffering, but the cases in which relief has been given are very few, compared with those in which no good has been accomplished by operation and in many of these the condition of the patient has been rendered worse. I believe that the reason for failure to accomplish more by surgical means in tuberculosis of the bladder is the fact that when the bladder has become involved the disease in other parts of the uro-genital tract has progressed too far to warrant any surgical interference.

It has been possible in the time at my disposal to present very imperfectly only a few points in regard to uro-genital tuberculosis, and these have been presented more for the purpose of suggesting the extent of the subject than of answering the many questions which are met with by every investigator in this department of pathology. There are but few of these questions to which we can at present give positive answer, and there are few fields of scientific research which have been so little explored. I hope that the observations which I have made may at least be suggestive, and may possibly stimulate others to enter this field of research.

PROGRESSIVE PERNICIOUS ANEMIA.[1]

By ALFRED STENGEL, M.D.,
OF PHILADELPHIA;
PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

Within the limits of this discussion, I cannot hope to consider in every detail the subject that has been assigned to me. Fortunately, there are certain aspects of this question which at the present day require no discussion, being so universally recognized as to be matters of common knowledge. For example, the symptomatology of the disease is so uniform that little has been added to the knowledge of it since the earliest descriptions of Addison. Practically the only exceptions of consequence are the minuter knowledge of the gastric manifestations, the recognition of certain intra-ocular signs and symptoms, and the group of nervous manifestations referable to the peripheral nerves and spinal cord that have been lately studied.

If, however, the symptomatology of the disease is well known, the etiology, the pathology, and the diagnosis are still grounds of dispute and uncertainty, and even the definition requires careful consideration.

What shall be considered as a practical definition of this disease? Addison regarded it as a form of progressive anemia without definite cause, and Biermer practically agreed with him. At the present time the majority of observers are disposed to include in the category of pernicious anemia cases which are not progressive in character, but, on the contrary, are distinctly relapsing, and cases in which the etiology is more or less clear. Looking at the subject from another point of view, it may be recalled that some years ago the disease was described as primary when it was thought that the essential feature was a disturbance of the blood-making organs, as the result of which the integrity of the blood suffered deterioration. In view of the observations of Quincke, Hunter and others, this view is untenable, and the abnormal condition of the bone-marrow, first discovered by Pepper in 1872 and since regarded as the most constant lesion of the disease, is quite generally looked upon as secondary and not characteristic. It is known that in all forms of destruction of the blood, the bone-marrow and the other lymphadenoid tissues hypertrophy in the attempt to compensate for the loss of corpuscles. This leads to the production of new blood cells, more or less immature, and it has been the view of many that the processes in the bone-marrow in pernicious anemia, while perhaps more active and at the same time productive of less mature corpuscles, because more rapidly evolved, are otherwise identical with the processes that occur in all forms of cachexia in which the bone-marrow is called upon to increase its normal activity. Ehrlich and some of his pupils have maintained, on the contrary, that there is a distinct form of activity in the marrow

[1] Read at the seventeenth annual meeting of the New York State Medical Association, held in New York, October 15, 16, 17, 18, 1900.

in pernicious anemia to which he would give the term megaloblastic, and that this does not occur in other forms of anemia or cachexia. The only answer that can be made to this is that Ehrlich's view rests upon no scientific demonstration excepting that a certain form of nucleated red cell is common in pernicious anemia and rare in other forms of anemia or cachexia.

In the light of our present evidence, it is certain that the disease under discussion results from rapid destruction of red blood-corpuscles for which the blood-making functions do not suffice to compensate. Moreover, it is practically settled that the source of the hemolytic agents is the gastrointestinal tract. In the case of pernicious anemia resulting from the presence of *bothriocephalus latus* in the intestines or from invasion of this tract by other parasites, there is certainly little doubt of the operation of toxic agents; while in more obscure cases the discovery of atrophic conditions of the mucosa, ulcerations, or cancer, makes it seem likely that similar poisons are generated and occasion the blood-destruction that initiates the disease. If these considerations are admitted, and it may be said with little reservation that they are established, pernicious anemia is a secondary condition and not a disease. It remains, however, to note this important fact: Not every subject having *bothriocephalus* in his intestines develops pernicious anemia, and the disease does not invariably follow upon the grave gastrointestinal conditions alluded to. It is possible that in certain cases a special sort of infection may be superadded to the primary conditions or that the hemogenetic function of the bone-marrow in certain persons is deficient or perverted. The latter seems to me the more likely view because, in the first place, no definite proof of a coincident infection has been discovered, and, in the second place, the characters of the blood in pernicious anemia suggest a profound disturbance of hemogenesis.

There are still a few authorities who believe or assert that pernicious anemia is a primary disease and that there is no such thing as secondary pernicious anemia. The evidence in favor of this position is entirely negative and wholly inadequate. A careful review of established facts warrants no other conclusion than that which I had occasion to state in a paper on the "Treatment of Pernicious Anemia" in 1896 in the following words: "As far as our knowledge of the disease extends to-day, it is but a symptomatic disorder of the blood and not a disease in the strict sense. It matters not whether a cause is discovered or not; whether there be gastrointestinal lesions, parasites in the intestines, pregnancy or parturition, or no discoverable cause, the resulting condition of the blood, the symptoms, the course and tendency to fatal termination, and the general post-mortem lesions are the same, and I can therefore see no justification for setting apart a group of cases as true Addisonian pernicious anemia, and calling all those in which causes are found severe secondary anemia." Practically, the same view is expressed by Ehrlich in his monograph published in 1900 (Ehrlich & Lazarus, Nothnagel's Series) in these words: "We must, however, always remember that we are not dealing with a disease *sui generis*, but with a frequently recurring symptom-complex which may accompany a variety of diseases." In consequence of these views it is necessary to look upon pernicious anemia as a secondary disorder with a characteristic clinical course and with certain peculiar blood changes.

I may not consume time by detailing the clinical features of the disease, but will refer only to a quotation from Addison's monograph to which Pepper first alluded in his important paper published in 1872. Addison says: "For a long period I had from time to time met with a very remarkable form of general anemia occurring without any discoverable cause whatever—cases in which there had been no previous loss of blood, no exhausting diarrhea, no chlorosis, no purpura, no renal, splenic, miasmatic, glandular, strumous or malignant disease." And further on: "It makes its approach in so slow and insidious a manner that the patient can hardly fix a date to the earliest feeling of that languor which is shortly to become so extreme. The countenance gets pale, the whites of the eyes become pearly, the general frame flabby rather than wasted, the pulse perhaps large, but remarkably soft and compressible, and occasionally with a slight jerk, especially under the slightest excitement. There is an increasing indisposition to exertion, with an uncomfortable feeling of faintness or breathlessness on attempting it; the heart is readily made to palpitate; the whole surface of the body presents a blanched, smooth and waxy appearance; the lips, tongue and gums seem bloodless, the flabbiness of the solids increases, the appetite fails, extreme languor and faintness supervene; breathlessness and palpitations are produced by the most trifling exertion or emotion; some slight edema is probably perceived about the ankles; the debility becomes extreme, the patient can no longer rise from bed, the mind occasionally wanders, he falls into a prostrate and half-torpid state, and at length expires; nevertheless, to the very last, and after a sickness of several months' duration, the bulkiness of the general frame and the amount of obesity often present a most striking contrast to the failure and exhaustion observable in every other respect." It must be added to this description that irregular and occasionally continued fever is a frequent symptom, that gastric and intestinal symptoms, such as vomiting and diarrhea, are common, and that ophthalmic examinations usually reveal hemorrhages in the retina. With these brief statements, I must leave the subject of symptomatology to proceed with that of the hematological features.

Examination of the blood discloses several more or less characteristic abnormalities: (1) The number of red blood-corpuscles is reduced below the number seen in any other condition;

(2) the red corpuscles present varied and marked alterations of shape, size, character, and staining relations; (3) the hemoglobin, while greatly reduced in amount, is often in excess relatively to the number of the corpuscles and is very rarely diminished more than the corpuscles, the "globular richesse" of Hayem therefore being usually at par or plus and very rarely much below par; (4) the total number of leucocytes is usually reduced and the mononuclear elements, especially the smaller forms, are nearly always relatively more numerous than the polymorphous cells or, in other words, the total leucocytic reduction occurs at the expense of the polymorphous leucocytes.

Let me now refer in detail, but briefly, to some of these facts: The number of red corpuscles and the percentage of hemoglobin have been regarded as most essential factors in diagnosis by Hayem and Laache, while Ehrlich has sought to minimize their importance as compared with his own methods of morphological study of the cells. A strictly impartial student must admit that a continuation of the two methods is necessary to a certain diagnosis. I have seen a few cases in which a sole reliance upon the enumeration of the red cells and the estimation of the hemoglobin would have led to erroneous conclusions, and have, on the other hand, found some in which the morphological diagnosis would have been uncertain. As a result of my experience, I would conclude that there are very few cases, if any, of conditions other than pernicious anemia in which the number of corpuscles is below 1,500,000 and the hemoglobin approximately equal in percentage to that of the corpuscles. There are cases of cancerous cachexia and post-hemorrhagic anemia in which such profound reduction of the number of corpuscles does occur, but in these the amount of hemoglobin is reduced to even greater degrees. Looking at the other side of the question, we may regard as fairly established the following facts: (1) Poikilocytosis reaches its highest grades in pernicious anemia; (2) macrocytes and an average excess in size of the red corpuscles are more common in this than in any other disease; (3) polychromatophilia and macrocytosis are more striking in this disease than in any other; (4) megaloblasts are more abundant and more regularly present in pernicious anemia than in other forms of anemia; and (5) a combination of all these factors practically assures the diagnosis. It cannot, however, be asserted that any one of these conditions makes the diagnosis certain, and it is no longer regarded as proper to establish the diagnosis upon any one of these factors with the possible exception of the presence of megaloblasts. Ehrlich states that the "positive demonstration of undoubted megaloblasts in combination with the presence in abundance of megalocytes is indicative of pernicious anemia, since these conditions proclaim without question that the embryonal type of blood-formation has superseded the adult variety, even if but limited areas of the marrow are so affected." This statement is singularly elastic. Its acceptance requires agreement upon the question of what constitutes an "undoubted" (unzweifelhaft) megaloblast, and what must be regarded as "abundance" (reichlicherem Auftreten) of megalocytes. Taking it, however, at its most rigid interpretation the statement is erroneous. I have seen two cases of leukemia which during an interval of aleucocytosis must have been regarded as instances of pernicious anemia according to Ehrlich's view, and several other cases of profound anemia in childhood would have been similarly diagnosed. Of course, I am prepared to admit that Ehrlich's statement may be accepted for the great majority of cases, but would insist that the exceptions be admitted and the statement be less dogmatic.

In less definite fashion, Ehrlich, and those who have followed him, would make it appear that a preponderance of large red corpuscles (megalocytes) and the predominance of megaloblasts, when there are both normoblasts and megaloblasts, are necessary conditions to establish the diagnosis of pernicious anemia. This view also seems to me unwarranted. I have seen cases of what in every other respect must have been regarded as progressive pernicious anemia (and one at least in which autopsy confirmed the diagnosis) in which during the entire clinical course of the disease repeated examinations had discovered abundant normoblasts with comparatively few megaloblasts. It must be remembered in connection with this statement that the definition of a megaloblast is uncertain and that the criterion by which Ehrlich has sought to classify the erythroblast, namely, the size and morphological properties of the nucleus, is not admitted by others. According to this mode of differentiation many of the cells which I have habitually regarded as normoblasts would naturally fall into Ehrlich's group of megaloblasts. It is difficult on this account to reach any practical conclusions as to the validity of his views, but it is certain that in the cases to which I have alluded normoblasts outnumbered megaloblasts, even with the strictest interpretation of Ehrlich's definition.

For my own part, I do not pretend to arrive at the diagnosis of this disease by any one condition or by any limited number of conditions. It is as necessary in the case of pernicious anemia as in that of any other systematic disorder to take into account the clinical course and history as well as the results of special laboratory investigations. There is a disposition in some quarters to withhold the diagnosis of pernicious anemia, except in such cases as present the blood-count of a most extreme anemia, while, on the other hand, some others are inclined to make the diagnosis when the blood-count and the general condition of the patient are seemingly but slightly affected and when few large megalocytes and possibly megaloblasts have been discovered. Neither of these methods of diagnosis seems to me judicious. Pernicious anemia can undoubt-

edly be recognized at stages prior to the extreme reduction in the number of corpuscles and when the patient is still in a comparatively good state of health, and, in some instances, during intervals of apparent cure the blood-picture and the physical examination reveal sufficient evidence to justify the diagnosis, although the patient is then seen for the first time. While this is true, I believe that it is unwise to hazard the diagnosis in cases in which the blood-count is but slightly altered merely upon the discovery of a few abnormal cells, even of such cells as I have referred to—megaloblasts. I am inclined to stand upon the opinion I expressed in a paper on "Nature and Diagnosis of the Disease," read before the Philadelphia County Medical Society in May, 1894, and I would quote from that paper as follows:

"My own observation leads me to regard as pernicious anemia any case presenting suspicious clinical features in which the red corpuscles number less than 1,500,000 per cubic millimeter, and in which the hemoglobin shows about the same proportionate reduction. The diagnosis becomes certain in cases in which the hemoglobin is relatively in excess, and in which great alteration in the size and shape of the red corpuscles and the presence of large nucleated red corpuscles are observed. In addition to these characters of the blood, pernicious anemia presents a train of clinical manifestations scarcely to be mistaken when present in their typical form."

I cannot dwell further upon the matter of diagnosis and wish now to pass on to some considerations regarding prognosis. I have not seen a patient with pernicious anemia who has been cured. I doubt the diagnosis in the case of Hayem, the only one in the literature which may, according to Ehrlich, be looked upon as one of permanent cure of the disease. One of my cases has been under my observation since 1892 and is still in good health. Several other cases in my experience have remained in fair health for as much as four or five years, but I have never seen nor known of a case in which it could be reasonably supposed that the disease was cured.

While the prognosis *quoad vitam* is hopeless, the outlook *quoad valetudinem* is often quite hopeful. Many cases of pernicious anemia may improve spontaneously from time to time, and the intervals of comparative freedom from discomfort may be as long as several months or even a year or more. Medicinal treatment unquestionably aids in securing this favorable outcome and when a period of improvement has set in, the continued use of proper remedies secures for the patient the continuance of his favorable condition.

No case of this disease is sufficiently serious to warrant a hopeless feeling regarding its treatment. I have several times seen temporary recovery take place when the patient was reduced to the last point of anemia, was comatose and unable to take or retain food.

I wish to say one word here regarding the alterations in the blood-count. I am aware that certain authors have reported remarkable, sudden improvements in the character of the blood. It is not reasonable to suppose that these are due to sudden formation of large numbers of red corpuscles; on the contrary, the probable explanation is found in the assumption of an alteration in the distribution of the corpuscles or a reduction in the quantity of serum. Some have referred to the improvement in the blood after attacks of diarrhea. It is entirely conceivable that such increase in the number of the corpuscles may be the result of inspissation of the blood through a loss of serum. Even the character of the corpuscles may have changed and the cells may assume a more normal appearance. This, however, may also result from a thicker, more normal condition of the serum. Improvements in the character of the blood to fairly normal conditions may, however, actually occur from a restoration of the hemogenetic function, but such improvements are recognized as more settled by their persistent progressive character.

TREATMENT OF TYPHOID FEVER.[1]

By STEPHEN SMITH BURT, A.M., M.D.,
OF NEW YORK;
PROFESSOR OF PHYSICAL DIAGNOSIS AND CLINICAL MEDICINE IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

Inasmuch as the personal equation cannot be eliminated from a patient with typhoid fever, all stereotyped methods of treatment are open to criticism, and although it will always be typhoid fever, the affection varies with the individual and the environment, and great are these variations. We have to consider carefully the fundamental power of resistance, as well as to estimate the probable extent of the infection. We have to deal with the peculiarities of constitution or temperament of each patient, equally with the disease, and to be guided by his idiosyncrasies. Consequently we must treat the individual who has the typhoid fever rather than the typhoid fever to the exclusion of other considerations.

There are several important principles regarding the management of this disease. The patient must be put to bed at once and there be kept until an advanced period of convalescence; this is of the utmost importance. Those victims of the disease who struggle against fate, and go about for a week or ten days, are very prone to a fatal termination; and those who by any mischance get out of their beds are greatly in danger of death in various ways. One young man who continued to keep up and to attend to his daily duties well into the second week of typhoid fever, despite many ominous warnings, died of intestinal hemorrhages within eight days after he finally took to his bed. An acquaintance of mine allowed his patient to travel several hundred miles at the beginning of an attack, in order

[1] Read before the Newport (R. I.) Medical Society, July 17, 1900.

to reach home, and this error in judgment resulted fatally as might have been expected. A young boy who got out of bed and walked to the end of the ward in a semi-delirium during the absence of the nurse, some years ago at Roosevelt Hospital, fell and died of a ruptured spleen. Sometimes toward the end of the fever, when the heart is at its lowest ebb, there will be a collapse from a premature attempt to assume the upright position.

The food must be of a nature that can be easily assimilated, and that will not irritate the intestinal tract by the coarseness of what remains to be excreted. While there is a difference of opinion as to what is the most judicious kind of food, my experience and possibly my prejudices strongly incline me to a fluid dietary. Certainly too much solid nutriment has been the cause of death. I recall a painful example of the sudden death of a patient who was well on the road to recovery, and who was surreptitiously given some grapes to eat by a well-meaning but inconsiderate friend. Water should be freely administered; it undoubtedly flushes the tissues and assists elimination. Fresh air must be provided in abundance, for it supplies the waste-matter in the pulmonary circulation with a means of oxidation. And now we have reached a point where it is a question what further should be done in addition to the regular routine nursing. Simplicity should be our aim in the management of typhoid fever. In fact, the more a physician departs from this standard the farther he is apt to be removed from a high order of intelligence. The mild cases will recover without any medication.

The malignant infections commonly will result in death in spite of all treatment, while those that occupy an intermediate position will often be saved through well-designed measures. Possibly some of the very best results can be shown in the entire absence of medication, but I should not consider it wise to advocate, to the exclusion of all else, the expectant treatment. Nor can it be called strictly scientific to undertake to force this, that, or the other exclusive method upon the profession. For a working hypothesis it is well to assume that Nature performs the greater part of the recuperative process, and that the less meddling the better, barring accidents. When the patient has been placed under the conditions already discussed, he occupies a position somewhat analogous to one who has had a broken limb reset and placed in splints. The knitting is done by a natural process, if it is done at all, and not by the surgeon.

About ten years ago, in a paper on the "Prevention and Treatment of Typhoid Fever," which was read by me before the Medical Society of the State of New York, I quoted from Flint's Practice of Medicine the death-rate of 307 cases treated by Dr. Cotting of Boston without drugs of any kind. It was ten per cent. I likewise referred to the 250 cases of typhus fever treated at Bellevue Hospital by Alonzo Clark. At this time there were as many more cases under the care of his colleagues, and among these there was a great mortality. "Although it was winter, the windows were removed, stoves were placed before the open spaces to warm the incoming air, and, except for moderate stimulation, no medicine was given. Not one of the 250 cases died, and in two weeks they were convalescent." In acknowledging the receipt of a reprint of my paper, the late Dr. William Halle Walshe of London said, apropos of these statistics, that having been a student of the great Louis, in Paris, he had always taken a deep interest in the subject of typhoid fever, and that at one time he made an investigation of the mortality of all the principal hospitals in Europe and found by far the best results were obtained at the Hotel Dieu, in Paris, where the death-rate was only 5 per cent. and the treatment was entirely without medication. What is more, Dr. Walshe did me the honor of telling me that he was wholly in accord with my views on this vital subject.

Students now and then ask for an opinion of the merits of the so-termed Woodbridge method of treating typhoid fever. It is reported that during the Spanish war a board of medical officers at Fort Meyer Hospital found in 57 cases treated by Woodbridge himself, and he was afforded every facility for the experiment, the mortality was 10 per cent., while of all cases treated otherwise it was but 7 per cent. There were in all about 600 cases treated at this time.

The question is sometimes asked me, "Do you pursue the alcohol treatment?" To which of course I reply that alcohol is used when it is required. My belief is, however, that often alcohol is much more freely and extensively used than is necessary. Once there were three cases being treated in the same ward of a hospital with which I was connected, whereof one was taking no stimulant, one was taking a little wine, and another needed and received the best part of a quart of whiskey every twenty-four hours for over two months; all recovered. In the '70's there was a time when the tub-bath, which has recently been much in evidence, was quite extensively employed. There was a patient in my hospital with a temperature ranging from 104° to 105° F., and a pulse running along at 60 per minute; his legs and arms as well as his body were covered with a rose-colored eruption. He was systematically tubbed, but he died nevertheless. The conclusions drawn from that and many other trials of the system have since inclined me to considerable caution in my selection of candidates for this kind of treatment.

The temperature does not disturb me as much as the nervous symptoms, which are a better index of the gravity of the situation, and there seems to be nothing so soothing to meet these conditions as some form of cold-water application. But it need seldom be an actual tub-bath. Anything that puts such a strain upon a patient *as to require free stimulation in consequence* had better not be employed indiscrim-

inately. A sponge-bath of one-third alcohol and two-thirds cold water thoroughly carried out, in the majority of instances, will accomplish the desired results with considerably less expenditure of strength on the part of the patient. If this is not sufficient a more copious application of water, called the slush-bath, may be employed. And then there is the wet pack together with the sprinkler. Some cases, however, will have high fever and practically no nervous symptoms, and their condition may never become very alarming.

Many years ago I advanced the proposition that fever is probably a conservative process and that while it remains within bounds it should not be the object of much solicitation. It is owing to our ignorance of this matter that we have been guilty, in times not long past, of so much meddlesome interference. The thermometer has its uses and is invaluable, yet it becomes dangerous in the hands of those who are unable rightly to interpret its revelations. In all my experience I have never been open to the charge of ordering a dose of antipyrin, or its congeners as an antipyretic in typhoid fever. My last patient has just recovered after a six-weeks' illness. His temperature during the second week rose to 104° F., and once, in the early morning, strange to say, it reached 105° F. His blood reacted quickly to the Widal test. Rose-colored spots appeared in crops upon his arms, legs and body, in profusion. Still, his pulse remained good and there were no nervous symptoms. His only medication, some dilute sulphuric acid, and a little calomel on the first day, might easily have been omitted. The rest of the treatment consisted in cold sponge-baths every two hours as long as his temperature remained above 102.4° F., which it continued to do for a short period to the contrary notwithstanding. In my opinion the safest intestinal antiseptic remedies, if any are to be tried, are mild laxatives. And for moving the bowels ordinarily a rectal injection. One of the worst cases of hemorrhage that I have encountered was treated successfully by ice to the abdomen and quarter-grain doses of powdered opium every fifteen minutes until controlled. There were three separate copious hemorrhages. When the bowels move more than three or four times in twenty-four hours, subnitrate of bismuth in large doses, alone or with small doses of morphine, will often be all that is required. Strychnine, ammonia, alcohol, and ether are the supporting remedies to be relied on when indicated. We must be guided by our estimate of the condition of the patient's muscular system, including the heart, as to how much he shall be allowed to do when the fever has gone and when the time comes for getting up. In my opinion he should be kept on a soft diet for a week or ten days. At all events, we must feel our way, always leaning to the side of caution in relation to his regimen in those dangerous and trying days of the patient's convalescence.

INCREASING THE THERAPEUTIC VALUE OF COD-LIVER OIL BY THE ADDITION OF FREE IODINE AND FREE PHOSPHORUS.[1]

By LOUIS J. LAUTENBACH, A.M., M.D., PH.D.,

OF PHILADELPHIA;

SURGEON-IN-CHARGE OF THE PHILADELPHIA EYE, EAR, NOSE AND THROAT INSTITUTE; NOSE AND THROAT PHYSICIAN TO THE ODD FELLOWS' HOME; LATE CHIEF OF EYE CLINIC OF THE GERMAN HOSPITAL.

COD-LIVER oil, the oil of the liver of the *Gadus morrhua,* has been a much used remedy for rheumatism, scrofulous and wasting diseases for centuries, but only within the past century has it become a standard remedy with the medical profession. Many have been the preparations introduced as substitutes, but nevertheless it still stands preeminent and really alone in its special field—a field which in our opinion cannot be said to be entirely dependent upon the fatty ingredients of the oil, nor upon its halogen constituents, nor upon its nerve-building property.

The purposes of this paper are to compare the modern cod-liver oil with the cod-liver oils of the time prior to 1853 and to discuss the seeming relative loss in therapeutic action of the newer oils, and also to endeavor to explain the cause of this loss as well as a means for overcoming it. When the Icelander or the Norwegian of the long ago went fishing for cod he brought in his catch, packed the livers in barrels and headed up the barrels. He continued doing this all the season, which usually lasted for about three months. After the season was over he opened the barrels and skimmed off the floating oil. Of course by this time, even in those cold regions, the livers were in an advanced stage of decomposition. This oil was the best oil of those days and was usually a light yellow color and known as raw *medicinal oil.* By continuing this process more oil, but of a darker shade of color, was obtained and this was known as *pale oil.* Later on when the putrefaction became further advanced the oil became a browner color, and this oil, called *light-brown oil,* was drawn off and kept separate from the former. When no more oil could be squeezed out, the residue was heated in a cauldron far beyond the boiling-point and the oil thus obtained was known as *brown oil* and was rarely used medicinally, being employed in the arts, especially for tanning processes, etc. Indeed, even the variety known as the *light-brown oil* was often rejected for internal medicinal purposes. Of the above-mentioned varieties of oil all were contaminated by the putrefactive process. Only one variety—the brown oil—was subjected to the influences of heat.

Since the introduction of the Möller[1] steam process in 1853 the method of obtaining the oil has all been changed. As the oil is prepared today in Norway, at the celebrated fishing grounds of Lofoten and Romsdalen, the livers are taken usually within six or eight hours after the cod has been caught and subjected to this process.

[1] Read before the Section on Therapeutics and Materia Medica of the American Medical Association, Atlantic City, N. J., June 5–8, 1900.

At both these places the fishing season extends from January to April, and as the thermometer then generally registers below freezing, there is no chance for decomposition to occur between the catch and the preparation of the oil. At the fisheries of Newfoundland and Massachusetts and at those on the Shetland Islands and the Eastern coast of Scotland, as well as those on the coast of Russia and in Iceland, the fisheries being carried on at a considerable distance from the land, and at the two places first mentioned during the hot season, it necessarily follows that putrefaction must occur before the oil is prepared.

By the steam process the livers are heated over a large water-bath, or in jacketed cauldrons, or, when the process is carried on aboard ship, in an open inverted cone of wood, the purpose being to relieve the livers of all the contained oil by means of a temperature not above 180° F. To-day the old processes have been supplanted by this steam process.

With reference to the normal composition of the oil of to-day, no one has given the subject a more thorough study than F. Peckel Möller[2], who has published a work of some 492 pages, the index of which contains nearly 3000 titles. It is considered by far the most complete exposition of the subject that has ever been presented.

By a study of this and of the other chemical researches on the subject, we are at once convinced that we are dealing with a most complex organic body containing, one might almost say, numberless constituents. Möller classified the components of cod-liver oil as follows: Hydrocarbons; oxygen compounds; combinations of oxygen compounds; oxygen cyclo-compounds; halogen compounds; sulphur compounds; nitrogen compounds; proteids; ptomains and leucomains; toxins and antitoxins; ferments. The oil which he studied is one peculiarly free from putrefactive compounds, on account of being made at once from the fresh livers, and is peculiarly free from adulterations such as might arise from the use of the livers of other fish, as in the Norwegian waters during the cod season practically no other fish exist. The cod abound and destroy all the other fish, whereas, in the Newfoundland, Massachusetts, Scotland and Russian fisheries the cod, the pike, the haddock, the ling, the whiting, and many others, even the shark, are frequently caught and their livers are probably used in the preparation of the oil. How much more complicated may be the chemical composition of such a mixture, especially when subjected to the usual putrefactive processes, I know not.

As to what may be the active principle or principles of this complex body there has been much discussion, and we seem to be as far from a satisfactory solution as half a century ago. At various times various ingredients have been so designated, in their turn the title has been given to the supposed alkaloids, to the morrhuol, the iodine and bromine, to the trimethylamine, to the contained fat, to the phosphorus, as well as to many other of its constituents. No doubt it has no single body which can represent the sum total of its activities, but must be considered as a complex organic body whose therapeutic effects, while evident, are yet withal a multiple action.

The therapeutic virtues of cod-liver oil are within certain lines peculiar to itself. Its effects on patients with struma, scrofula, tuberculosis, syphilis, rheumatism, gout, rachitic and nervous affections, as well as on sufferers from wasting diseases, are marked and typical; no other agent producing exactly the same effects, no other or combination of oils or of other constituents bringing about the same general results. Its alterative, tissue-building and tissue-repairing, as well as general nourishing qualities are marvelous, but as to just how these results are brought about we can but theorize.

In partial explanation of its action is the fact that in the case of no other known oil are osmosis and endosmosis so rapid. It is emulsified more rapidly than any other known fat in the presence of pancreatic juice and glycerin without any gum. It is thus more easily digested than any other known oil and possesses, therefore, greater nutrient qualities. If this were all of its beneficial properties it would in its sphere be without a peer, but when, in addition to the nutrient and digestive function, we observe its prompt alterative effects, we must be convinced that we are dealing with a therapeutic agent which, while not thoroughly understood, has for ages been of incalculable value to the human race and one whose virtues can probably never be thoroughly explained.

Its nerve-building energies are perhaps in a great part due to the phosphorus it contains, making it extremely valuable for shattered nervous systems as well as in rachitic cases; its prompt and thorough alterative effects observable in the strumous, scrofulous, phthisical and rheumatic are due probably to the contained iodine and bromine, as well as perhaps to other constituents the therapeutic value of which is not known.

When we try to compare the virtues of the old oil with that now manufactured, I think there are several facts which indicate that the former was therapeutically the more efficacious. In my boyhood I took cod-liver oil daily for months at a time extending over a period of several years. In those days the two oils were in competition, the steam-prepared, yellow oil was the more pleasant to the taste and to smell, but our "family doctor," as well as all of our experienced friends, advised the old, browner more odorous and more fishy oil; the consequence was I began early to inquire why there was any need to take the more disagreeable oil. All I learned was that its effects were more prompt and more thorough, that in the opinion of the older doctors of that day the new oil was deficient in some of the healing virtues of the old, and their belief was so universal that I early became convinced that this was a truth and not merely a prejudice.

Tending to the same conclusion, if we look over the medical literature of the period of 1855 to 1870, we find that as the old oil gave way to the new, numerous manufacturers placed preparations of cod-liver oil on the market purporting to be fortified with one or more of its active principles, especially do we notice *iodized oil, phosphorized oil*[3], used in varying strengths up to ¼ grain to the ounce of oil, and *brominized oil*. It is significant, to say the least, that this flood of fortified oils should appear at this time immediately after the adoption of the new steam process. It would seem that some lack in the new oil must have been detected at once. This endeavor to improve on the nutrient and alterative virtues of the new cod-liver oil continues to quite an extent even up to the present day.

Between the new and the old oils there are but two fundamental differences. (1) The old oils contained a much greater proportion of the decomposition products, such as the alkaloids[4], than the new oil. These alkaloids are by some considered as abnormal[5] and by others as the active principles.[6] (2) The old oils necessarily retained more of their volatile constituents than the new oils, as in the process of preparation of all the old medicinal oils no heat of any kind was used, subsidence and pressure only being the means of expression, whereas all of the new oils are subjected to a long-continued heat of about 180° F., and often much above this point; thus the volatile constituents, especially the halogens and the phosphorus, are in great part removed in the preparation of all the modern cod-liver oil.

Convinced of the above facts, some years ago I began to contrast the therapeutic effects of the new oils as compared with the same oil fortified by the addition of iodine, bromine and phosphorus, and I was soon satisfied that their addition seemed to intensify the normal therapeutic virtues of the oil. Later on, not being convinced of the distinctive value of the bromine in the preparation, I omitted it, retaining only the iodine and phosphorus.

Feeling sure of my position in this matter, I gave my formula to a Philadelphia druggist with the request to so combine these elements with the oil as to retain its normal pale color while endeavoring to improve both the odor and palatability.

As the result of our experiments we succeeded in producing a preparation which we have designated, *Oleum Morrhuae Iodi-Phosphoratum*, a clear, light-yellow oil, flowing perhaps more freely than most good oils, having less of the fishy and less of the hydroxylation odor than usual and a much less marked fishy taste. Each tablespoonful of this oil is fortified with one-one-hundredth of a grain of pure free phosphorus and one-twelfth of a grain of pure free iodine, neither ingredient being at all noticeable either to taste, sight or smell, and yet by the method of ultimate analytical analysis all recoverable therefrom.

As having perhaps an important bearing on this question, I will call attention to an alterative preparation rather extensively used in our city, quite constantly by the late Dr. Pepper and by him sometimes called a summer substitute for cod-liver oil. I refer to *Vini Iodi Comp.*, each teaspoonful of which contains one-one-hundredth of a grain of free phosphorus and one-sixth of a grain each of free iodine and bromine. It is typically an alterative. It has little or no effect upon the bodily weight, except inasmuch as it stimulates growth by restoring to the tissues healthy action. In no sense is it a nutrient and thus differs markedly from cod-liver oil. It is extremely valuable as a substitute for all those patients usually benefited by cod-liver oil, who, on account of the extreme heat of the summer or a temporarily abnormal sensitiveness of the stomach-walls or a nervous excitability of the palate, are unable for the time to take oil. It seems to have all the virtues of the oil without its nourishing and fattening qualities.

I have found this fortified oil more easily taken than others. It is less repulsive to the taste and smell, and in many cases patients soon learn to like its taste as well as its effects. It is more easily digested and much less liable to be followed by eructations. This increased digestibility is no doubt due to the soothing influences of the iodine on the stomach-walls. It is more prompt in its systematic effects in building up the tissues. Its alterative effects are more prompt and more pronounced. The prescription reads as follows:

℞ Olei Morrhuæ Iodo-phosphoratum, Oi.
S. One tablespoonful at night, only on retiring, preferably followed by a taste of lemon.

For a period of perhaps seven years I have constantly been prescribing it, using it in a thousand or more cases, and I have had but two or three instances in which patients insisted that they could not take it. I have not observed a single case in which it had a bad effect, and in every case I believe I noticed an advantageous effect markedly beyond that which I formerly observed in similar cases when using the plain oil in equal quantity. I have named it *Iodo-Phosphorized Cod-Liver Oil*, and usually write my prescriptions as here noted, rarely ordering it to be taken more than once a day and then at bedtime. When necessary to use it oftener I prescribe it at meal-time in addition, but I do this rarely. Occasionally I have the patient take a little whisky with the oil, but almost invariably advise that a piece of lemon be used after taking the oil.

I believe this matter of prescribing the oil at night, the last thing at night just before slipping into bed and taking the lemon thereafter, to be a very important one to the patient, making its administration more pleasant and its digestion more rapid.

This preparation of *oleum morrhuae iodi-phosphoratum* is a perfectly stable preparation made

agreeable by the addition of aromatics, containing 95 per cent. of pure Lofoten cod-liver oil, each ounce containing one-sixth of a grain of pure free iodine and one-fiftieth of a grain of pure free phosphorus. It will keep indefinitely if stored in a cool place and tightly corked, but, like all cod-liver oils, if kept too long, for a few years, for instance, or exposed to the light, the fatty acids become oxidized, in other words, hydroxylation occurs and the oil then becomes unpleasant to the stomach.

No cod-liver oil, however, can be expected to keep well without hydroxylation for a much greater period than a year after its preparation, and this preparation of *oleum morrhuae iodophosphoratum* must in this respect be judged by the ordinary standards. Convinced that, if this preparation be tried faithfully and used as advised, it will meet with approval, I take pleasure in recommending it to the notice of the profession.

MEDICAL PROGRESS.

Inhibition of Heart in Diagnosis.—After discussing the methods employed by various investigators in producing cardiac inhibition, and the results obtained by them, Albert Abrams (*Phila. Med. Jour.*, September 29, 1900) says that in his experience inhibition of the heart is best attained, for clinical purposes, by voluntary, forcible contraction of the muscles of the neck. This maneuver is easily learned, even by children. If too much exertion is employed in contracting the muscles of the neck the result will be acceleration, not inhibition, of the heart-movements. In the case of those patients who cannot learn the maneuver, the writer places a long, narrow cushion under their chin and directs them to press with all their might on the cushion with their chin. By this maneuver the heart's action is not stopped, but there is obtained an inhibition of the intensity of the heart-tones. Abrams cites seven cases illustrating the value of the inhibition maneuver as an aid to diagnosis and presents the following essential facts as the result of his investigations: (1) The inhibition maneuver will cause organic cardiac murmurs to become faint and in exceptional cases will render them inaudible. (2) Transmitted murmurs are more amenable to the maneuver. (3) The fainter the murmur, the more easily is it suppressed by the maneuver. (4) When a transmitted murmur can be inhibited, the tone which it masks can be auscultated. (5) Heart-tones are less amenable than are heart-murmurs to inhibition. (6) Hemic murmurs are more readily inhibited than are the organic murmurs. (7) Usually the murmurs of anemia may be suppressed, and their evanescence is marked by the reappearance of tones. (8) Exocardial murmurs are easily influenced by the inhibition maneuver. (9) When the inhibition maneuver is incorrectly executed, the result is to increase the intensity of the murmurs owing to increased exertion which intensifies the heart's action. (10) The inhibition maneuver when often repeated is futile in its results owing to overstimulation of the vagi. (11) In irregular action of the heart or in delirium cordis, the inhibition maneuver, by momentarily inhibiting the rapidity of the heart, renders signal service in determining the time of a murmur; the effect of the maneuver being practically like that of digitalis. (12) The inhibition maneuver enables us to determine the condition of the vagi as inhibitors of the heart and guides us in the use of cardiotonics.

Mesenteric Cysts.—Upon these relatively rare occurrences, C. N. Dowd (*Annals of Surgery*, October, 1900) suggests these data. The diagnosis is rather difficult because the cyst is commonly freely movable and gives tympanitic resonance on all sides of itself, and in the uncomplicated cases is not connected with the pelvic organs. The symptoms are chiefly those of the mechanical presence of the cyst, namely, pain from pressure, constipation and vomiting, occasionally emaciation ascribed as a rule to interference with the chylous return. The prognosis corresponds with the facts that these cysts are to be considered among the serious abdominal tumors, and that they are usually so situated as to be rather easily removable. When practicable exploratory incision and ablation are indicated, when removal is impracticable suture to the abdominal parieties, evacuation and drainage are necessary. Jessett has successfully enucleated a cyst and resected a portion of the intestine included in its wall, just as has been done with solid mesenteric growths. As to the pathogenesis the following summary is stated: (1) A multilocular cyst-adenoma of the transverse mesocolon, containing pseudo-mucin exactly like a cyst-adenoma of the ovary, suggests its probable origin as an embryonic ovarian sequestration; (2) dermoid cysts in the same situs suggest the same embryonic source; (3) chylous cysts in the mesentery, whose contents are chyle and whose walls contain lymphatic vessels, indicate embryonic cysts into which an effusion of chyle has occurred; (4) sanguineous cysts appear to be cysts into which hemorrhage has occurred; but hematomata of the mesentery should not be described as sanguineous cysts; (5) cysts whose walls resemble intestine are evidently sequestrations therefrom; (6) serous cysts are usually similar to the classes above but are not usually in the paths of the lacteal vessels; (7) hydatid cysts are a class by themselves and are due solely to the tenia ecchinococcus; (8) reports indicate

that these cysts are encountered at least once per month. If examination were made of its contents and walls probably the whole matter would soon be cleared up; (9) probably the whole pathogenesis can be explained as either embryonic, hydatid or malignant.

Ammonio-Formaldehyde.—This drug may be used in the form of urotropin, cystogen, or ammonioform, with uniform effect. The more important effects of urotropin, as exploited in Germany and in this country, give rise to the following axioms: (1) The effects of urotropin are almost entirely confined to the urinary passages. (2) These effects are due, in part at least, to the liberation of formaldehyde in the urine. (3) These effects are heightened acidity, marked antiseptic properties, and variable irritation of the neck of the bladder. Edward L. Keyes, Jr., (*Phila. Med. Jour.*, September 29, 1900) discusses some of the advantages of the drug and certain limitations to its usefulness and suggests a practical way of handling it to the best advantage. Fifteen to forty-five grains are usually given as the daily dose, and most writers say that if the daily dose be kept below thirty grains the irritation, the pollakiuria, and dysuria will not appear. Keyes reports a number of cases illustrating some of the variations in the action of urotropin in different cases. Case I. had had paralysis of the bladder, with cystitis and pyelitis, for about thirty years. Seven and a half grains of urotropin three times a day caused serious vesical irritation. Later fifteen grains daily cleared the urine of bacteria and all shreds, but twenty grains doubled the deposit and caused some irritation. Any remission in the administration of the urotropin in this case was followed by a reappearance of the bacteriuria, while fifteen grains kept the urine clean. In Case II. forty-five grains were given daily for nine days without any vesical irritation. The drug was then given in a daily dose of fifteen grains for a month, at the end of which time there were no bacteria or albumin present. The urine has remained clean for two weeks at this date. The writer thinks the difference in these two cases, as to the vesical irritation, is one of idiosyncrasy. After giving urotropin the writer has been able to dilate strictures without causing a chill, and he habitually employs the drug in cases in which urinary chill or septicemia are present or threatening, especially in operative work. Case III. illustrated the post-operative diuretic effect which Keyes has observed in a number of cases. He has, however, never known urotropin to have any diuretic or other beneficial effect on chronic uremia. In Case IV. a wound caused by a suprapubic prostatectomy sloughed and did not heal because of formalin irritation due to the fifteen grains of urotropin which the patient was taking daily. On substituting salol for the urotropin improvement and, eventually, healing took place. From his experience in other cases, the writer believes that this patient exhibited an idiosyncrasy. Keyes sums up his conclusions as follows: (1) Urotropin seems to be almost a specific in some cases of uncomplicated acute catarrhal pyelitis. (2) To prove effective it may have to be administered in large doses until the urine is practically free from bacteria, after which a smaller dose may be sufficient. (3) In judging the effects of the drug, the centrifuge and the microscope should be employed. (4) The dose must not be sufficient to cause pollakiuria and dysuria by irritation of the neck of the bladder. (5) The possibility of such an irritation cannot be overlooked even when small doses are given. (6) Urotropin is extremely serviceable as a prophylactic of the various forms of urinary septicemia and urethral chill. (7) Its routine employment both before and after operations on the urinary passages is indicated. (8) The urine containing urotropin occasionally has an escharotic effect upon wounds which may constitute a contraindication to its use.

Primary Renal Tuberculosis.—O. G. Ramsay (*Annals of Surgery*, October, 1900) formulates the following conclusions upon this subject: (1) That primary renal tuberculosis may be classed as a semi-malignant form of inflammation, and that for this reason surgical treatment is always indicated. (2) That this surgical treatment will have a palliative or a curative end in view depending upon the condition of the patient and the extent of the local pathological process. (3) That nephrotomy in renal tuberculous processes is to be designated as a palliative operation with the chief aim of the immediate relief of grave symptoms, and that it does not preclude a secondary nephrectomy, and that coupled with free evacuation and drainage of abscesses is a most valuable procedure. (4) That resection of a diseased portion of a tuberculous kidney is a most dangerous procedure, because it is not always possible to take out all the disease and a focus so left behind may infect the other kidney or the system at large or both. (5) That nephrectomy or nephro-ureterectomy is distinctly indicated in every suitable case and in suitable cases should result in permanent cure in 55.5 per cent. of all cases. (6) That the indications against nephrectomy are tuberculous disease of the other kidney or of other organs in the body. (7) That tuberculous disease of the bladder is not to be considered a contraindication to nephrectomy because it will probably heal later. (8) That a small tuberculous focus in the lung, provided the patient is otherwise well, is not to be considered as a contraindication. (9) That in cases of doubt as to whether a patient can stand an immediate nephrectomy, it is best to do a nephrotomy and leave the nephrectomy to a later date. (10) That the clamp method of managing the pedicle is contraindicated on account of the danger of hemorrhage upon removing the clamp. (11) That it is safest to remove the ureter with the kidney, as a persistent fistula may give trouble if it be allowed to remain in the body. (12) That the majority of these fistulæ tend to heal

either after the removal of a deep suture or after the slow disappearance of tubercular disease along the ureter, which then becomes a fibrous cord. (13) That we may expect an increasing number of cures as our means of diagnosis improve and our surgical technic is carried out more scientifically and carefully.

Some Cardiac Conditions.—The most inferior and posterior portion of the heart, writes W. H. Porter (*Post-Graduate,* September, 1900), is the left auricle, and from it the blood flows to the ventricle from right to left, forward, and usually upward, toward the junction of fourth rib and cartilage. All organic valvular lesions come under five headings, *viz.*: Congenital malformations, acute and chronic endocarditis, acute and chronic dilatation of the cavities, rupture of a valve-segment, and rupture of the chordæ tendinæ. In mitral regurgitation the murmur is produced by some of the blood flowing back from one full cavity to another full cavity having less blood-pressure. If the blood-pressure in the ventricle falls until equal that in the auricle, the murmur disappears, to reappear when the tone of the ventricle is restored. This systolic murmur is transmitted to the left, usually lost at the anterior axillary line, and heard again posteriorly midway between the angle of the left scapula and the vertebræ. The presystolic murmur of mitral stenosis is really a systolic murmur of the left auricle; if the muscular power becomes enfeebled the murmur may entirely disappear, and with the resumption of power it is reestablished. This murmur and that of aortic stenosis are produced by blood flowing in its normal direction; the murmurs of regurgitation, by blood flowing against the normal current. A presystolic murmur without alteration in structure of the mitral valve may occur with aortic incompetency if the rapidly regurgitated blood reaching the left ventricle floats up a segment of the mitral valve so as to cause partial obstruction. It not infrequently happens that a mitral systolic murmur persists in life, but autopsy shows no mitral lesion. The insufficiency may have been due to unequal innervation, or unequal nutrition of the papillary muscles, causing one to allow its valve-segment to float too far into the auricle and thus producing a gap. The treatment of cardiac lesions should be directed to establishing a higher nutritive condition in the heart, and throughout the whole system; for when hypertrophy takes place to produce compensation, there is no corresponding augmentation of the blood-supply to the heart muscle, and degeneration follows, with dilatation and finally lack of compensation.

Epidermolysis Bullosa.—A case of this rare and unique affection is reported by C. P. Russell (*Jour. Cutaneous and Genito-Urinary Dis.,* September, 1900). The patient was a boy, eight years of age, born in Alaska. He has always been strong and well. Has had no diseases except measles when he was two years old. From the history it is probable that he has had the present disease for five or six years. The history is that he has been troubled almost constantly with recurring large and small bullæ, forming usually over the joints or wherever the integument is tightly stretched. These bullæ, in nearly every instance over a joint, occur most frequently in response to a slight bruise or blow. Some of these bullæ, especially those not directly over a joint, seemed to have arisen spontaneously. The knuckles of both hands have always been a favorite location for the formation of the bullæ. On the knuckles the bullæ vary in size from a split pea to a dime, but about the wrists and ankles they are sometimes as large as a half dollar, while over the knees they are three or more inches in diameter and form a large bulging sac distended with a straw-colored serum. It has been noticed by the boy's guardian that preceding the formation of an unusually large bullæ there would be a slight swelling and raising of the skin, with some congestion. The lower extremities have been most effected. A very slight knock or pressure on the skin is sufficient to cause a bulla. The bullæ are of very irregular shape primarily, and their irregularity not being due to the fusion of two or more, is characteristic of this disease. The boy presents no other symptoms of any sort, except marked hyperidrosis. He perspires freely even in winter. This profuse perspiration has been a marked feature in nearly all cases hitherto reported. In many cases heredity seems to be an etiological factor, but no such influence can be traced in this case. An illustration, showing the character of the lesions, accompanies the report.

Prostatectomy.—The technic of this operation, claims H. Mynter (*Annals of Surgery,* October, 1900), should be improved especially by avoiding suprapubic cystotomy or laparotomy in order to crowd the organ down to the operative field, and thus obviating the shock of the operation and the prolonged after-treatment in bed, to say nothing of the other greater risks. In a patient of his, weighing two hundred and forty pounds and except for the prostatic diseases perfectly healthy, he followed this method. The usual straight anteroposterior perineal incision was met by a semicircular one embracing the anus and close to it. The rectum was next freed and the prostate, well in view all the time, was crowded down by a hand above the symphysis pubis. A stone-searcher occupied and outlined the urethra. Enucleation of all the lobes was accomplished without deliberate opening of the bladder or the urethra. The urethra was accidentally torn between the sound and the finger-nail toward the end of the operation. This necessitated the drainage and the long after-treatment which would otherwise have been avoided. This tear can be escaped beyond doubt, the writer thinks. Where cystitis makes drainage necessary, a permanent catheter can be tried, or, failing in that, the urethra can be opened later in the perineum well forward. The removed prostate in this case weighed 2¾ ounces.

THERAPEUTIC HINTS.

Influenza.—H. C. Wood recommends the following:

℞ Antipyrin ..... 1.0 (gr. xv)
Pilocarpin. muriat..... 0.03 (gr. ss)
Tinct. aconiti..... 0.25 (gtt. viij)
Aquæ q. s. ad..... 45.0 (℥iss).

Dose: A tablespoonful followed by a general bath or foot-bath lasting ten minutes; after this, the patient is put to bed, and a dessertspoonful given in a glass of hot toddy, to be repeated in twenty minutes unless sweating occurs before. If there is much pain, 0.01 gram (gr. 1/6) of morphine may be added to the mixture.

Chronic Parenchymatous Nephritis.—It is this form of nephritis, writes James Tyson, which gives rise to the intense anemia so characteristic, and iron and other tonics must be administered. Much of the headache, general discomfort, and constipation, however, is due to too large doses of iron, and this should never be given in sufficient amount to blacken the stools. Basham's Mixture is valuable, or the following, in which the amount of iron may be varied and enough acetic acid added to make a solution:

℞ Tinct. ferri chloridi..... 4.0 (℥i)
Liq. ammon. acetat.....120.0 (℥iv)
Acidi acetici q. s. ad. solv.
M. Sig., a dessertspoonful night and morning, freely diluted.

Strychnine is an admirable adjuvant tonic to the iron, and may be dissolved in the same mixture. —*Amer. Text-Book of Applied Therapeutics.*

Calomel in Hemorrhoids.—This drug is not only curative, but also prevents the phlebitis which causes so much pain. For external hemorrhoids give laxatives, and powder with calomel; for internal hemorrhoids use calomel suppositories or an ointment of

℞ Calomel ..... 2.0 (gr. xxx)
Vaseline .....
Lanoline .....aa. 15.0 (℥ss).

Add belladonna or opium if desired. Wash anus with boric-acid water after each defecation.—*Jour. de Méd. de Bordeaux,* Sept. 23, 1900.

Chronic Constipation.—The formula for Hinkle's cathartic pill is:

℞ Cascarin .....
Aloin .....aa. 0.015 (gr. ¼)
Gingerine .....
Ext. belladon.....aa. 0.008 (gr. ⅛)
Podophyllin ..... 0.01 (gr. 1/6)
Strychnine ..... 0.001 (gr. 1/60).

Dose: One three times a day, or one or two at bedtime.

Prolapse of Rectum.—For loose sphincter with slight prolapse in a child of two years, Jacobi advised faradism for four or five minutes each day, hypodermics of strychnine sulphate, 0.001 gram (gr. 1/60), every second day, and the local application of five- to ten-per-cent. ext. nux vomica ointment, a piece the size of a pea after each defecation. For the prolapse of sessile polypi, he orders the insertion of a piece of ice, injections of ice-water, and a lotion of one- to two-per-cent. tannic-acid or alum solution.

Acute Rheumatism.—A useful lotion to be applied to the inflamed joints on warm lint is that of Dr. Fuller:

℞ Tinct. opii..... 30.0 (℥i)
Potass. carbonatis..... 15.0 (℥ss)
Glycerini ..... 60.0 (℥ij)
Aquæ .....270.0 (℥ix)

The dressing should not be covered by any impermeable material.—*Amer. Text-Book of Applied Therapeutics.*

Purulent Pleurisy.—Capitan at once aspirates all the fluid possible; if it returns, he again removes it and injects a few drops of camphor and betanaphtol, equal parts, or some peroxide of hydrogen. If the pus then persists, an opening is made under cocaine, by knife or thermocautery, and drainage established. He agrees with Desplats that the operation is simple and that removal of rib is unnecessary. As anesthetic and to avoid cardiac or respiratory difficulties a good injection is 1.0-2.0 cc. (♏ xv-xxx) of

℞ Cocainæ hydrochlor.... 0.10 (gr. iss)
Morph. hydrochlor.... 0.05 (gr. ¾)
Sparteinæ sulphat..... 0.20 (gr. iij)
Atropinæ sulphat..... 0.02 (gr. 1/3)
Aq. dest. q. s. ad..... 10.0 (℥iiss).

This is supplemented by ethyl-chloride spray. At the first sign of trouble inject:

℞ Sparteinæ sulphat..... 0.05 (gr. ¾)
Caffeinæ .....
Sod. benzoat.....aa. 0.20 (gr. iij)
Aq. dest..... 1.0 (♏ xv).

Repeat if necessary. He lays stress on not operating till the deposits of fibrin have become loosened from the pleura. Normally a certain dulness and indistinct breathing persist after aspiration, and when this disappears above the level of the reaccumulating fluid, it indicates detachment of the fibrin. The results of operation are satisfactory in empyemas due to pneumococcus, streptococcus, or staphylococcus, but not in those of tubercular origin.—*La Méd. Mod.,* Sept. 5, 1900.

Chronic Bronchitis.—In the majority of cases the derivatives of tar, turpentine and balsams are the most efficient expectorants. They are specially indicated in relaxed conditions of the mucous membranes, with excessive secretion, in combination as follows:

℞ Ol. Terebinthinæ } ..... aa ♏ 20
Picis Liquidæ... }
Ol. Eucalypti ..... ♏ 50
Balsami Tolutani ..... ℥ 1½
Benzosol ..... ℥ 4.

M. et disp. in caps. No. 60. Sig. One four or five times a day.—*Butler, Medical Standard.*

THE NEW YORK STATE MEDICAL ASSOCIATION.

The seventeenth annual meeting of the New York State Medical Association, held on Monday, Tuesday, Wednesday and Thursday of this week at the New York Academy of Medicine, was the most successful gathering in the history of this organization.

This Association has been pushing its way into the front ranks on straightforward and praiseworthy lines, and the high standards it has steadily advocated have tended to make a centralized and harmonized body capable of exerting much valuable influence on the medical interests of the country.

The meeting was attended by over three hundred members and delegates from every region of the State and the social and scientific features were unusually well managed and attractive. The rule of twenty-minute papers was adhered to in a manner that reflected much credit on the President of the Association.

The symposium on Obstetrics was practical and brought out a number of papers of much value, that on the Blood was marked by a series of studies of great interest and importance. A number of these we will present to our readers. The group of papers on Tuberculosis was characterized by breadth of treatment, as most of the organs of the body were considered in their relation to the tuberculous process.

Taken as a representative meeting of the State Association, its officers and well-wishers can be proud of the showing made.

HEMATOLOGY AND DIAGNOSIS.

The examination of the blood constitutes one of the most important features in the scientific medicine of to-day. Scarcely known ten years ago beyond the confines of physiology, the study of hematology has now by steady elaboration, mainly in the hands of Hayem, Ehrlich, Thayer and Cabot, assumed a prominent position in the thought and practice of scientific physicians. The symposium on the blood given before the New York State Medical Association this week is another evidence of that wide interest taken in the subject by all progressive physicians ever ready to make use of the most recent acquisitions of scientific investigation.

In the discussion at this meeting questions mainly of clinical interest were considered. During the course of his remarks on the technic of blood examination, Dr. Edward K. Dunham of New York pointed out the well-known sources of error in the estimation of hemoglobin by the Fleischl instrument usually employed. Variations in the diffusion of the coloring principle and the element of personal equation in the comparison of the tint obtained constitute the more serious inaccuracies in the estimation; the latter alone, in the speaker's opinion, amounts to at least five per cent.

Appreciation of the value of blood-tests in surgical practice is still of very recent date. This is one of the most promising sides for future research in work of this kind. Many points in diagnosis were ably discussed at this meeting by Dr. Bloodgood of Johns Hopkins University. The author, as a result of his careful studies of the leucocyte count with reference to abdominal surgery, was able to formulate some valuable conclusions with regard to appendicitis, peritonitis and intestinal obstruction. By the leucocyte estimation alone he showed that an earlier diagnosis, always of importance in these conditions, was often possible. A high leucocytosis is evidently almost always present in acute appendicitis, being particularly high when the appendix is distended with pus or in the gangrenous forms. With an increase in the severity of the symptoms there is usually a corresponding in-

crease in the leucocytosis; with amelioration the count usually falls quite rapidly. A rising leucocytosis with symptoms of appendicitis is then always a serious indication. With a count of over 20,000 under these conditions Dr. Bloodgood urges immediate operation; gangrene, abscess formation, or peritonitis have probably already begun. In cases with a recent history of appendicitis and a high leucocyte count, the probabilities are that abscess formation has occurred; however, absence of leucocytosis does not exclude such a condition.

It is agreed that the leucocyte count rises with the increase in the acute peritonitis; however, just before death a rapid fall occurs very often, a condition sometimes very confusing, for just such a thing occurs with abatement of the peritoneal inflammation. Dr. Bloodgood has particularly investigated typhoid peritonitis in this connection; his results are of great practical value. Dr. Thayer and he have found that any rise of the white cells in typhoid fever almost invariably indicates some definite inflammatory complication. And peritonitis is no exception to this rule. With a rapidly rising count and abdominal distress the diagnosis of perforation may be considered highly probable.

The most recent views regarding pernicious anæmia and leukemia were ably considered by Drs. Stengel and White of the University of Pennsylvania. With the exception of some contributions to the gastrointestinal lesions and detail to the other symptoms the masterly description of pernicious anemia by Addison stands today just as it did then. Dr. Stengel regards the disease as a toxic affair, probably of gastrointestinal origin. The blood-pictures in this disease and leukemia were long supposed to possess specific diagnostic features; Drs. Stengel and White, however, both showed, as others have already done, that a consideration of all phases of the blood examination associated with the clinical history are necessary for an accurate and intelligent interpretation of the condition.

The malarial parasites in their connection with blood examination were discussed by Dr. Le Wald of New York City. A very complete exposition of the mosquito theory of infection as enunciated by Manson and his followers was given. The speaker accepted their main conclusions *in toto*.

The value of blood examination in the diagnosis of trichinosis, already exploited by Brown, Thayer, Blumer and others, again received further confirmation by the studies of Dr. Gordinier of Troy, N. Y. He reported two cases with complete blood examinations; the well-known increase of the eosinophiles which occurs in this disease alone made possible the probable diagnosis, verified later by other methods.

When methods for the determination of the germicidal and protective powers of the serum will have been devised, then, indeed, will we seemingly have reached the utmost point in one of the richest fields of study. With the progress of the times, it seems not unreasonable to believe that this will shortly be forthcoming.

THE HEALTH OF CITY DWELLERS.

In the innocence of youth we used to imagine that there was no health within city walls. We even shared the delusion which possesses so many foreign artists and makes them portray the American urbanite as an attenuated conglomeration of skin and bones; as one, in fact, whose incessant pursuit of the elusive dollar has brought him to such a sad state of physical, mental and moral decrepitude that he is fit only to serve as a horrible example to mankind. On the other hand, the tiller of the soil stood—in our young fancy—as the very incarnation of health. For us all farmers were round and ruddy, their helpmeets buxom and prolific, their offspring freckled and strong-limbed.

What havoc the evolutional realities of the past few decades have played with the fancies of the artist and the child! And all because the city dweller has learned to give due heed to the laws of hygiene. He has discovered the vast importance of municipal and domestic sanitation, the equally great value of proper food and clothing, and the absolute necessity of interrupting the routine of toil with a proper modicum of play in the open air.

It is upon the importance of this rapidly increasing tendency of the city dweller to play out-of-doors that we wish to dilate. Never before in the history of this country has Nature cast such a spell over him in such a sane, wholly commendable way. She has no great living disciple like Thoreau, who can convert people to her so eloquently as almost to persuade them—as Rousseau did—to go on all fours. Nor would the city dweller of to-day listen to such a sermonizer upon Nature. He is eclectic in his tendencies, knows the value of cosmopolitanism to a mind of healthy

growth, and compromises with Nature by taking certain courses at her school. These courses are of a peripatetic order of a peculiarly healthful type, in that it is the student and not the teacher who does the walking about. Now, if the booksellers' announcements are any index, the number electing these courses this last spring must have been enormous, for on every hand we were met by the statements that popular treatises on birds, and trees, and wild flowers were selling in the thirty thousands. What the resultant rambles in the open mean in the way of pleasurable emotion and delicious fatigue to the purchasers of these books we leave to our readers to surmise.

Of all the many artifices by which Nature decoys the city dweller to her haunts for a time and gives him health and pleasure in return for his neglected work, lack of space forbids even the mention. For some years now the camera craze (salutary madness!) has been upon us and set our motor activities toward the open. It has excited to a high pitch our roving instincts and awakened our appreciation of Nature's choicest beauties. Even the trolley car, dread juggernaut, deserves to have its therapeutic value weighed in the balance with its deadly propensities. It has taken us to charming suburbs where, between lunch and dinner, we might fill our lungs with the uncontaminated air of heaven and see wild things growing, and hear the song of birds. The bicycle, much abused instrument of health, certainly should have its meed of praise. On the whole it has been of immense value to the city dweller as a means of exercise in the open and has enabled him to escape for varying periods of time out of the ruts of daily life.

What we owe to the game of golf as a factor in the maintenance of the city dweller's health cannot easily be estimated. Never has a game been introduced into this country which has so quickly secured such a powerful hold upon persons of all ages and nearly all conditions. It takes its devotees out-of-doors under the most ideal circumstances imaginable and requires no greater expenditure of energy than they are perfectly safe in making.

The dress reform which has followed in the wake of the widespread tendency among urbanites toward the open is in itself worthy of the physician's warm approval. Look at the shirt-waisted and short-skirted young woman of to-day as, with bare head and bronzed bare arms, she pursues the wayward golf ball over hill and dale. Her movements are as lithe and free as those of a young animal, and her indifference to the elements is superb. Contrast her with the representative of the same social stratum of a few years ago—the "pale and interesting" young woman with a penchant for syncope and sour edibles—and see if we have not gained vastly by the change. The ideal types of young American womanly and manly beauty which the artist, C. D. Gibson, created ten or more years ago are fast becoming a commonplace reality in cities, and the reason therefor is none other than the now nearly universal out-door-play tendency of the age. To foresee the vast evolutional import of this tendency to coming generations requires no great measure of discernment.

How has it fared meantime with "the man with the hoe"? If we were to judge from the innumerable testimonials from rural dwellers as to the efficacy of patent nerve invigorators and dyspepsia annihilators, which appear in the daily and religious press with ever-increasing and exasperating frequency, we should say "not well." But this conclusion may be unjust. It may be affirmed, however, without fear of cavil that for some good reason—bad cooking, monotony of occupation, lack of intellectual intercourse with the outside world or what not—the round and ruddy farmer, with his ample-bosomed spouse and freckled offspring, is about as scarce nowadays as the dodo.

ECHOES AND NEWS.

NEW YORK.

Illness of Dr. Sayre.—It is reported that Dr. Reginald H. Sayre is sick with typhoid fever.

Poisoning by Fly Paper.—A case of poisoning due to the licking of fly paper is reported by the daily press as having occurred at Matamoras, N. Y., in a young child. The main symptom observed was convulsions.

Plague Serum from Paris.—When the bubonic plague appeared in Glasgow, Dr. A. H. Doty, health officer of the Port of New York, ordered a quantity of plague serum from the Pasteur Institute, at Paris, as a precautionary measure for use at Quarantine in the event of the plague being brought to this country. The serum arrived some days ago and is now in the Quarantine Laboratory.

Unique Cause of Insanity.—An autopsy performed at Bellevue this week on a man who had

developed insanity within a comparatively recent time, revealed two bullets, one within the cranial cavity. The history of the case showed that he had probably tried to commit suicide, but had failed in the attempt, and had developed an insanity as the result of the traumatism.

Razorless Shave Damages.—As the result of using a patent remedy advertised to take off the hair without the use of a razor, a citizen of this city not only lost his beard, but a large amount of the skin of his face. He is suing for $2000 damages. The preparation is probably one of the many combinations of arsenic and potash.

New York Obstetrical Society.—At the annual meeting of this Society held Tuesday, October 9, 1900, the following officers were elected for the ensuing year: President, H. J. Boldt, M.D.; First Vice-President, Ralph Waldo, M.D.; Second Vice-President, H. N. Vineberg, M.D.; Recording Secretary, G. L. Brodhead, M.D.; Assistant Recording Secretary, G. G. Ward, Jr., M.D.; Corresponding Secretary, E. E. Tull, M.D.; Treasurer, J. Lee Morrill, M.D., and Pathologist, W. S. Stone, M.D.

Obituary.—Dr. Franklin Smith, seventy-six years old, died at his home, 366 Broome Street, one Tuesday night, October 9, 1900, after a short illness. He was born in this State, and for over a quarter of a century had been a resident of this city. He was a graduate of the Medical Department of the New York University, and for twenty years was a school trustee in the Fourteenth Ward.

Dr. William R. Larkin died October 15th from apoplexy, after an illness of ten days, at his home, No. 328 St. Nicholas Avenue. He was forty-two years old and a graduate of Bellevue Hospital Medical College. He was one of the founders of the J. Hood Wright Hospital and a surgeon to the New York Fire Department for several years. A widow survives him.

Dispute Over Consumption Hospital Site.—At a joint meeting of the State Forest Preserve Board and the State Board of Health held in Albany, October 11th, to consider the Big Lake Clear site chosen by the hospital trustees, a number of arguments were heard pro and con. Many citizens who owned cottages in the lake region objected on the ground that it would work unnecessary injury to the large number of visitors who yearly spend their summer holidays in the Adirondacks. Such an institution, located in such a region, could not help but prove an offense to the large classes in the vicinity and injurious to the vested interests of many.

Adirondack Tuberculosis Hospital.—In an able letter to the *New York Times* Dr. Eugene Hodenpyl of this city defends the action of the trustees of the New York State Hospital for Consumptives in choosing the site they have in the Adirondacks. He says: "The principal objection to this site, it appears, is on the ground that the fogs, mists, and dampness from the lake would be injurious to consumptives. This would apply equally to almost every part of the Adirondacks. The amount of rainfall in the North Woods is greater than in other parts of the State, and the region is so abundantly supplied by lakes and streams that fogs and mists in the early mornings during certain seasons of the year are of common occurrence. It is in this very region that so many consumptives, rich and poor alike, on the advice of physicians, have sought for and often have regained their health. It is the consensus of opinion of physicians who have practised in the Adirondacks that the amount of dampness which obtains in this region is not detrimental to the health of consumptives. Pneumonia is seldom observed, and diseases commonly ascribed as being due to exposure to wet are less frequent than in many other parts of the State. The camps which are so frequently occupied by consumptives are almost invariably located on the banks of a lake. In fine, then, the trustees propose to locate their hospital in a region which for years has been regarded as a favorable one for consumptives, and where experience has demonstrated that the results obtained in properly selected cases compare favorably with those of almost any other climate in the world. Objection has been made, too, on the ground of expense of the proposed site. Doubtless other sites could have been bought for less money. It must be remembered, however, that a site suitable for the hospital must possess many advantages; and from what I know of the value of Adirondack property that which possesses many advantages can no longer be picked up for a trifle. Finally, the site has been objected to by some on account of its proximity to some of the summer camps and hotels! Lake Clear is three miles from Saranac Inn, on the Upper Saranac Lake, and is two miles in an air line through the woods from Upper St. Regis Lake, and is over five miles from that lake by road. There is abundant proof to show that at this distance there is not the slightest ground for apprehension on the score of possible infection of the inhabitants of these places. Again, it seems to me, that the proposed site is sufficiently removed from the homes of summer residents, so that no reasonable objection can be made that the institution may detract from the attractiveness and value of property. Indeed, I was told last summer by one of the trustees that no site would be considered which was liable to offend in any way surrounding property-owners. A number of otherwise desirable sites were condemned for this reason alone. The trustees have examined personally almost every possible site in the Adirondacks, spending a good deal of time in so doing. Politics, the schemes of individuals with land to sell, etc., had no place in this board. For my part, I believe they have acted wisely, and that, instead of criticising the State, the poor consumptive and the neighboring property-owner have good reason to commend the work already

accomplished for the New York State Hospital for Consumptives."

PHILADELPHIA.

Medico-Chirurgical College.—A complete change of policy and business management is to take place at this institution. Hon. E. M. Paxson, ex-Chief Justice of the Supreme Court of Pennsylvania, has been elected president. The majority of the board of trustees have been members of the faculty heretofore, but these are to be supplanted by laymen.

Rumored Gift to University.—It is stated that Mrs. Mitchell, wife of Dr. Weir Mitchell, is to give to the University a memorial of her daughter in the shape of an addition to the hospital, or of a separate building, for the treatment of contagious diseases. It is hoped the rumor is true, as Philadelphia is greatly in need of a pay hospital for contagious diseases. An institution has been chartered, but the opposition of citizens to the location of a building, as well as lack of funds, has prevented its further action.

Aseptic Ether Inhaler.—At a meeting of the County Medical Society October 10th Dr. Ernest La Place exhibited an appliance for the administration of ether which he has used for two years with great satisfaction. It consists of an ovoid metal cup with an inner covering of wire gauze, a pad of sterile gauze being placed between the two each time it is used, the holder having been boiled to render it sterile. A crucial opening in the metal allows the pouring of ether upon the gauze and a slight trough catches any overflow.

Hahnemann College.—Dr. Pemberton Dudley, Dean of the College, recently read a paper upon the present diminution in the mortality-rate of the city and its causes. He ascribes it mainly to the fact that the law takes cognizance of the sanitary condition of the people. The suppression of tuberculosis in dairy herds and the persistent teaching of the contagiousness of tuberculosis are having their effect. The more general employment of disinfection in communicable diseases and a better attention to personal hygiene are also important factors.

A Live Hospital.—The Children's Hospital of Germantown, although in existence but little more than one month, has opened a training school for nurses. It is the only absolutely free hospital of the kind in Philadelphia.

Mysterious Inmate of Almshouse.—A young man who is deaf and dumb and can neither read nor write has been at the Almshouse since August 3d, when he was picked up on the street penniless. From a baggage check in his possession and from a rude map which he draws the superintendent believes the man is from Virginia.

Health of the City.—The death-rate continues very low, diphtheria being the only contagious disease at all prevalent. The chief of the Bureau of Health, in order to maintain this desirable condition of affairs, is sending circulars to every physician in the city stating the rules regarding contagious diseases and urging their literal compliance with the same.

School Physicians.—The School Board is considering a resolution requesting Councils to make an appropriation for paying visiting physicians to the schools a yearly salary of $100 each. This is less than was supposed to be paid when the act making provision for such services went into effect. An appropriation for this purpose has never been secured, hence the resolution.

Philadelphia Hospital.—Drs. Simon Flexner and Joseph McFarland have been appointed pathologists to succeed Dr. H. W. Cattell, resigned. No one can be elected visiting physician unless he promises to give ward instructions or clinical teaching to students. This is in furtherance of the plan to utilize for teaching purposes the vast amount of material at the Almshouse.

CHICAGO.

The Chicago Eye, Ear, Nose and Throat College.—The capital stock of this College has been increased from $10,000 to $25,000, and its directors from three to five.

College of Physicians and Surgeons.—The opening exercises were held October 1st, the opening address being delivered by Dr. Robert H. Babcock.

Woman's Medical College.—The thirty-first annual session was opened October 1st, at which time addresses were delivered by Professors William E. Schroeder and Leonard L. Skelton.

The Cottage Hospital.—This institution was one of the first of its kind in the State. It is to have a new main building, which will be erected and equipped in accordance with modern ideas. The capacity of the group of buildings composing the hospital will be about 150 beds.

Meeting of State Board of Health.—The Board recently held its quarterly meeting. A report prepared by the State Bacteriologist was read, which maintained that the water has not been contaminated by the drainage canal. The report proves that St. Louis is not justified in its complaints against the drainage canal. The prevalence of diphtheria in many places in the State was especially considered, and in the opinion of the Board the spread of the disease, in the majority of cases at least, has been due to a lack of recognition of the malady. The Board concluded to carry the case which it instituted against Dr. W. Frank Cross to the State Supreme Court. The defendant is charged with unprofessional conduct for his connection with the so-called National College of Hygiene and the Independent Medical College.

Experimental Psychology and Criminology.—Miss Frances Kellor, of the University of Chicago, has a pet theory that criminality and heredity have nothing to do with each other, but holds that all criminal tendencies result from early home training and subsequent environment. With the difference between the criminal and the normal man established, she believes that by improving legislation criminality can be checked and the criminal reclaimed. She has fitted out a laboratory at the University of Chicago, and her investigations will include hard students, "flunkers," athletes, and society leaders. She says that by "anthropometric measurements of the face, head and body, and observations on cranial development and defects, it is found that members of the same family differ greatly, according to occupation and surroundings. Under the influences of education and culture, the head and body are found to change their shape, while a lack of all these, combined with dissipation, produces the physical characteristics of the criminal. Psychological tests show that in the senses, emotions and intellect, the criminal varies distinctly from the normal man. These are simply the means through which a man responds to his environment. Social conditions have the greatest influence."

GENERAL.

Marriage Reform.—The Tri-State Medical Society of Tennessee, Alabama and Georgia, at its recent annual meeting held last week, took steps to secure medical legislation in those three States for the purpose of regulating or prohibiting the marriage of habitual criminals, persons afflicted with incurable diseases, drunkards, and victims of harmful drugs.

Plague at Glasgow Checked.—All of the plague suspects have been dismissed, but twenty plague cases remain in the hospital at Glasgow. An official bulletin, dated Thursday, October 11th, says: "The outbreak has been completely checked. Twenty-one days have elapsed since the last case. The reception houses will be closed to-day."

British Steamer Carries Plague.—The British steamer "Highland Prince," from Antwerp August 30th, London September 7th, and Bahia October 4th, arrived at Montevideo October 14th with bubonic plague on board. Five deaths, including the captain and first officer, occurred during the voyage.

Study of Carcinoma in Germany.—The Committee for the Advancement of the Study of Carcinoma in Prussia is now distributing the lists of questions and other prints relating to the subject of its activity throughout the German Empire. The replies are to be returned during the current month and later collected.

Dr. Loew Goes to Japan.—Dr. Oscar Loew, for two years past connected with the Agricultural Department as expert in physiological chemistry, has resigned to accept a position as lecturer in the Agricultural College of the Imperial University at Tokio, Japan.

Jewish Consumptives' Home.—The Executive Committee of the Second District Grand Lodge of the B'nai B'rith met October 14th in Cincinnati to elect trustees for the new Home for Consumptives at Denver, Col. Twenty-nine trustees were elected for one year, among them being the following: Martin A. Marks, Cleveland; Edward Kolish, Richmond, Va.; Samuel Heavenrich, Detroit; A. Abraham, Brooklyn; Joseph Miller, Baltimore; Max Bamberger, Philadelphia; Hannah Beinstein and Emanuel Lehman, New York; Solomon Ginsberg, Buffalo, and Philip Hamburger, Pittsburg.

The Shah of Persia and Doctors.—The Shah of Persia while in Budapest consulted an eminent specialist and was informed that he was affected with heart trouble and that the condition of his kidneys would grow serious unless strict dieting was observed. The Shah remarked that he had consulted four doctors in France, three in England, several in Austria and one in Germany, and that not one of them had told him the truth as to his condition.

Brain-Jar of Military Step.—Dr. Colin, regimental physician in the French army, has published in *Health* the results of his investigations into the effects of regular marching in disciplined bodies upon soldiers. The regularity of the step causes the indefinite repetition of a shock of the bones and brain, infinitely more deleterious than an irregular walk, and to this regular repetition of the shock of the same parts of the body is due the peculiar aches, pains and illness of the troops. Dr. Colin's preventive is a rubber heel in all military boots. This heel has been tried at his instance in the French infantry, he says, and the result has been found to be a great relief to the soldiers.

Doctors' Contracts.—A reputable physician and surgeon residing and practising in the Province of Quebec made a contract to render professional services in one of the United States whose laws debarred him from engaging in the practice of medicine there. The contract was broken by the other party to it, and the doctor brought a suit against him in the Canadian courts to recover the value of the work which he had done under the agreement. The defendant interposed a defence setting up the illegality of the contract, as being an undertaking on the part of the plaintiff to practise medicine and surgery in a foreign State where it was unlawful for him to practise. This defence has finally proved successful, the court holding that no compensation is recoverable upon a contract of this character, which is pronounced illegal.

Obituary.—Dr. Benjamin Hussey West, one of the old graduates of Harvard University, died at Neponset, Mass., on Thursday, October 11,

1900. He was born in Nantucket, November 10, 1814, and was the son of Paul West, a lieutenant in the British Navy and commander of the ship "Cyrus." He graduated from Harvard in 1835 in the class with the late Bishop Williams of Connecticut, Judge E. R. Hoar, Amos A. Lawrence, John A. King and others who have been prominent in public life. Only five survivors of the class remain. He was graduated from the Harvard Medical School in 1838 and commenced professional life at Pawtucket. In the early '40s he went to California, where he remained for several years, being a member of the Committee of Safety during 1849. Later he was for many years head surgeon of the Pacific Mail Steamship Company.

Dr. Joseph L. Cutler, for fifty years one of the leading surgeons of Allegany County, died October 12th in Bolivar, N. Y., of uremic poisoning, at the age of seventy-one years. He was born in Moravia, N. Y., graduated from the University of New York in 1850, and the same year located in Bolivar. He served ten months as assistant surgeon of the 134th Regiment New York Infantry during the Civil War. He earned his money to attend college by teaching , and among his pupils at Moravia was John D. Rockefeller, the Standard Oil king, whose first teacher Dr. Cutler was. Dr. Cutler leaves a widow and two daughters.

Medical Course at Bowdoin.—On the recommendation of the faculty of Bowdoin College the Board of Overseers, at its last annual meeting, voted that the work in the first year of the Medical School in physiology and anatomy should be allowed to count as four courses each toward the degree of A.B. in the college. Conversely, work in the college in chemistry and biology will, without doubt, soon be allowed to count as courses in the Medical School. Although this movement is in line with the three years' degree agitation in the universities, it is noteworthy in the policy of Bowdoin. When, a year ago, the course in the Medical School of Maine was lengthened to four years, it was soon found that a combination of the academical and medical courses must be so arranged as to offer completion in seven years.

Non-Medical View of Carlsbad.—Clyde Fitch, the playwright, says of Carlsbad: "If any one ever writes a play at that place it will be on the order of one of the gloomy old mystical German tragedies. If ever there was a place saturated with deadly monotony and unmixed gloom it is Carlsbad. You are routed out of bed at 6 A. M., and wander with a funereal crowd to the springs. This cheerful mob is made up of sallow-faced men and women ever wearing a small glass hung by a strap. The conversation is redolent of medicine. At nine o'clock is breakfast. This repast consists of two thin pieces of meat and two thinner pieces of stale bread. Then the entire crowd climb a series of hills under orders until luncheon, when one gets a piece of steak and a few mouthfuls of one kind of vegetable. Then the same old hills are tackled again, only with less determination, and, with a little lolling about and more mutual diagnoses, the time wears around to a frugal dinner. Later on everybody gets a massage bath and goes to bed. Next day same old water, same old hills, and same old food. It is beneficial, but the remedy is almost as bad as the disease."

Patent Medicine Ethics.—At the meeting in Aachen of the Society for the Advancement of the Natural Sciences, H. His, Jr., advanced the following points regarding the endorsement by physicians of newly-discovered medicaments. (1) The relations between the manufacturers of and the endorsers for pharmacological and medical products ought to be adjusted and regulated by some central institution. (2) The signing and endorsing of such products should be for the personal information and benefit of the manufacturer, but never for publication by him. (3) Physicians should never recommend in the public lay prints newly-discovered medical products or food preparations. (4) There should be greater conservatism in the matter of subscribing to the merits of a new drug, and the publishing of such endorsement should be reserved exclusively to the technical publications and medical press. (5) The articles appearing in the medical journals should be protected as far as possible against reprint for purposes of advertisement. (6) To demand or receive pecuniary benefits from signatures, recommendations, endorsements or publications regarding new preparations is inadmissible. (7) Physicians whose inventions are set up for sale are responsible for the manner of advertising them.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, October 6, 1900.

THE OUTBREAK OF PLAGUE IN GLASGOW—LIMITATION OF THE CASES—GOOD RESULTS FROM YERSIN'S SERUM—PRECAUTIONS AGAINST SPREAD OF THE DISEASE BY RATS—THE SOUTH AFRICAN HOSPITAL COMMISSION—EVIDENCE OF LORD KITCHENER—INSANITY IN ENGLAND.

There are now in hospital in Glasgow 24 cases of plague and 2 doubtful cases, and 88 persons are under observation. So far 6 deaths have occurred since the beginning of the outbreak a month ago. Thus it will be seen that the outbreak shows little tendency to spread. Yersin's antiplague serum has been used in the treatment with apparently great benefit. For example, a man acutely ill came under observation in the early stage. The bubo was in the axilla. Forty cc. of serum were injected, half intravenously, half subcutaneously, with the result that the temperature fell 4° F. in six hours, the swelling and tenderness round the bubo were

greatly reduced and in the course of the day passed away. Two days later the patient felt almost well and the pain in the bubo had disappeared. In another case, a man was admitted to hospital on September 9th. He had suffered for a week from headache and malaise until September 8th, when he had a rigor and sickness. He was unconscious and had a temperature of 105.8° F. In the left axilla was a group of enlarged and acutely tender glands. Twenty cc. of serum were injected into one of the brachial veins and a like quantity into the subcutaneous tissue of the abdomen. After six hours there was slight perspiration and the temperature had fallen 4° F. The pain in the axilla and the edema were less. On the following day the temperature was 100° F. and the patient felt quite well and desired to get up. Elaborate precautions have been taken against the spread of the plague by rats. At Liverpool printed instructions have been issued to the masters of all vessels trading with Glasgow. Care is to be taken that rats are prevented from boarding the vessel while in dock at Glasgow, for this purpose a man must be stationed at each gangway and beat off any rodent that evinces a desire to come to Liverpool. Should, however, a rat succeed in taking the sea trip he will find fresh difficulties confronting him at Liverpool. A man stands guard here, too, at the gangway. A number of corrugated iron sheaths are supplied for fastening round the mooring ropes so that a rat who attempts to traverse these may lose his footing and fall into the water.

The Hospital Commission has continued its sittings at Johannesburg. Lord Kitchener declared that the cutting down of the hospital transport under the order of January 29th was absolutely necessary in order to quickly relieve Kimberley. Everything was cut down. The problem was, What could be carried with the available mules? The personnel of the field hospital was not cut down and worked well. He deprecated placing transport altogether under the charge of field hospitals and confirmed Lord Roberts' evidence with regard to the supplies brought to Bloemfontein; 1680 tons of medical stores were brought up—all that was possible under the circumstances. The activity of the enemy necessitated the troops being sent out, the field hospitals had to be emptied to accompany them, causing overcrowding. Surgeon-General Stevenson explained that the men had to lie in the field hospitals in their khaki uniforms as no provision was made for supplying the field hospitals with clothes. In Bloemfontein every building was taken which was capable of being worked by the personnel. He admitted that in Kroonstadt and Pretoria there was shortness of utensils, milk, bedding, etc. He had permission from Lord Roberts to purchase everything obtainable and he spent thousands of pounds. At Pietermaritzburg another sitting was held. Mr. Bale, Attorney-General of Natal and Chairman of the Association for the Relief of the Sick and Wounded, stated that he had visited all the hospitals and noticed nothing to cause complaint. He had heard that Fort Napier Hospital was unsuitable, as it was infested with vermin. He admitted that there was too much red tape. Sir William Stokes had told him that too much attention was paid to organization. Dr. Max Blieden, formerly civil surgeon in Fort Napier Hospital, said that the barracks there were full of nests of vermin. These insects were found under the patient's splints and some men suffered terribly therefrom. One enteric patient in delirium ran away saying he could not stand them. There was insufficiency of fresh milk and clean linen. The condition of the wards was sometimes scandalous. The orderlies were too few and some of them stole liquor intended for the patients.

At the annual meeting of the North Midland District Poor Conference Dr. J. M. Rhodes read a paper on "The Increase in the Numbers of the Certified Insane and the Necessity of Making Provision for Them." He said there were in England upward of 100,000 people who were legally declared of unsound mind—nearly double the number in 1869. It had been said that the rush and pressure of business is to-day so severe that there is a large increase in nervous diseases. But the Registrar-General's returns show that the ratio of deaths from nervous diseases has steadily diminished. It is true that the mortality from insanity and general paralysis of the insane has risen during the last twenty years from 68 to 114 per million, but against this may be set the fact that the deaths from the next most fatal nervous disease, epilepsy, have fallen from 117 to 85. The returns for the last ten years show that the number of pauper lunatics has been increasing by more than 2000 per annum; last year it was nearly 3000. But these figures cannot be taken as proving such a great increase of insanity. The system pursued in reference to the insane has changed. For the last twenty years there has been a growing confidence in the authorities, and consequently an increase in the number of insane placed under the control of the state. The percentage residing with relatives had fallen from 18.46 to 6.23.

PARALYSIS OF THE FIFTH AND SEVENTH CRANIAL NERVES—INTERMITTENT ORBITAL VARICES—TUMORS OF THE BASE OF THE SKULL—FRACTURES OF THE ASTRAGALUS AND TIBIA—PYLORECTOMY FOR NEOPLASM—ULCERATIONS OF THE CECUM—RADIOGRAPHS OF THE RESULTS OF TARSOCLASIS—FOREIGN BODY IN THE PRIMARY BRONCHI—OLD DISLOCATION OF THE HIP—ADHERENT UTERINE RETROVERSION—CANCER AND QUININE—CONGENITAL DISLOCATION OF THE HIP.

Gayet, at the Société de Chirurgie de Lyon, June 7, 1900, presented a patient from his service whose history may be epitomized as follows:

First attack of suppurative otitis media about two years ago; second invasion of the disease three months ago; after this second attack occurred a simultaneous paralysis of the right trigeminus and lower segments of the right facial nerves, with insensibility of the mucosæ and skin supplied by the fifth nerve, paresis of the masticator muscles of that side, neuroparalytic keratitis, paralysis of all the muscles innervated by the right facial nerve except the orbicularis which was only paretic to a small degree, and deviation of the uvula and the tongue to the opposite side. The interest of the case lies in its pathogenesis. The cause was evidently suppuration in the middle ear with extension to the nerves directly, but no satisfactory explanation can be advanced as to why only the inferior segments of the facial should have suffered.

Vincent said he had seen a similar case which he would later report.

Ruotte narrated the history of a twenty-nine-year-old gardener suffering from the following symptoms of intermittent exophthalmos of six months' duration. Each time he would stoop the eye would undergo enlargement, projection forward with obliteration of the sulcus between the globe and the superior and inferior orbital margins, and with bluish soft tumefaction of all the adjoining skin. Pressure on the jugular vein reproduced an analogous condition. The ophthalmoscope showed the veins of the fundus to be slightly enlarged. The condition was evidently orbital varicosities which might have been produced by the patient's profession. If the condition increased operative interference would be necessary.

Gayet had seen several examples of the same trouble. One of his patients had sustained a fracture of the base of the skull. Large varicosities of fundus developed but vision had not suffered thereby.

Vincent at the session of June 14th related the facts of a tumor of the base of the skull apparently springing from the antrum of Highmore without in the least affecting the nasal cavity, compromising the optic nerve of that side and filling the zygomatic fossa. It was removed by partial resection of the superior maxilla, accompanied by a very vigorous hemorrhage supposedly from the cavernous sinus, stopped by packing. Complete cure followed. Histologically the growth was a very vascular fibroma.

Ollier observed that such active bleeding need not involve opening a large trunk like the sinus. Vascular polypi, such as these tumors really are, bleed at the least touch. Tamponade always checks such hemorrhage in his experience. The ordinary source of these growths is the basilar apophysis, but there are many exceptions. The best, most direct and commodious access to them is gained by vertical osteotomy with plugging of the nose. Hemorrhage is then in full view and readily commanded.

Destot exhibited radiographs and contributed an observation of a cavalryman who was thrown from his horse and landed on both feet. He was unable to walk and was taken in the hospital, where he was kept at rest for three months. Radioscopy showed a fracture of the astragalus and a wedge-shaped fracture of the lower end of the tibia behind it.

Vallas stated that in bimalleolar fractures the third or tibial fragment is always due to tearing, according to Tillaux. This contribution showed that another force may operate, namely, direct pressure upward upon the tibia by the astragalus.

Rochet added that in experimental fractures he had often produced cuneiform fragments in the tibia by violence directly in the line of the limb.

A. Pollosson at the meeting held June 21st brought forward a twenty-four-year-old female upon whom he had performed pylorectomy for neoplasm which was situated in the neighborhood of the pylorus and epitheliomatous in type, with three small ganglia in the lesser omentum which had to be removed. The noteworthy point is the youth of the patient who had already been three times pregnant. Not long ago he introduced another young woman who having had four children suffered from a cancer of the uterus. The query is whether oft-repeated impregnation in the young may not tend to excite cancer. Statistics show that patients in the condition of this woman with pyloric cancer rarely live three months. Since she had exceeded this he felt the operation had been of benefit, although recurrence or metastasis was almost certain.

Vincent described ulcerations of the large intestine near the cecum which caused localized abscess and peritonitis without appendicular lesion except a little swelling. The child died without vomiting and with hypothermia. These facts deserve comparison with those evolved by Ollier and Moré-Josserand, who found that such abscesses often occur not as part of an appendicitis but as the result of perforating ulcers, whose source is in dispute, but which often resemble tuberculosis.

Vallas recalled a case where in the presence of a moderate appendicitis a perforating ulcer of the adjoining cecum was apparent, explained no doubt by a double and extensive infection of both the cecum and the appendix. When the course of such conditions is rapid and virulent, tuberculosis is scarcely to be thought of, because it usually attacks large areas of the bowel and proceeds slowly. Vincent's case appeared to have died of superacute peritonitis such as gives no vomiting and no typical signs of the disease.

Polosson raised the point that even in the case of Vincent the appendix could not have been normal because the extremity was enlarged. He recalled a patient of his, about sixty-five years old, who during the first ten days of a mild attack of probable appendicitis seemed perfectly well. Suddenly he passed by rectum a large quantity of bright blood. Recovery followed. Perhaps this bleeding was due to these cecal ulcers.

Vincent closed by saying that histologically the appendix was normal, which proved to his mind that such ulcers of the cecum occur as an independent pathological fact.

Radiographs were shown by Vincent of old operative cases for clubfoot by tarsoclasis. They justified his methods which had been characterized as brutal and barbarous. The function of these feet were still good after respectively five, seven, ten and eleven years since the operation. The photographs showed that he had produced fractures and subluxations about the astragalus and toward the dorsum of the foot. The observations will be published presently *in extenso*.

Goulliod at the meeting of June 28th described a case in which a twenty-month-old child had inspired a nail. Through a tracheotomy wound a strong electromagnet was introduced and the nail removed. It was seen to jump from the right primary bronchus where radioscopy had shown it to be to the poles of the magnet. It measured two inches.

The same author presented a case of iliac luxation of the hip unreduced for four months. Under anesthesia several futile attempts were made to reduce the dislocation by the ordinary flexion and abduction methods. Finally the forced abduction method of Lorenz was successful. After a three-weeks' immobilization in Bonnet's gutter splints recurrence was found. Reduction was again done in the same way and after careful and more prolonged immobilition the joint remained intact and good function returned.

Ollier said that authors give too dark a prognosis in dislocation of the hip. Not only are they reducible after several weeks but also after several months. He had returned the head of the bone to its socket eight months after its dislocation and obtained good function. In such cases very likely the head is only partially replaced, but the rule is for the resulting function to be far better than would be the outcome of a resection of the head.

Vallas pointed out sepsis as the great difficulty in the way of opening operations for the reduction of old dislocations. He therefore advised forcible reduction in all cases as a preliminary procedure. In a patient sixty-seven years old he had fractured the neck of the femur in an attempt to replace the bone. The net result was a much improved though not normal gait.

Durand had one failure at forced reduction which of itself passed from a pubic to an iliac type. This was the second case of the same thing he had had with a creditable result and good function in each.

Ollier enforced the utility of these powerful manipulations for tearing down adhesions, elongating the contractured muscles and ameliorating the position of the head. One may add to these baths, continuous traction and massage, and not resort to bloody operations except when nerves and vessels are evidently compressed, and give symptoms.

Fochier introduced a young woman who after an abortion four years ago had suffered from pelvic inflammation and then retroversion of the uterus with adhesions. She had subjected herself to various kinds of treatment for this condition, massage and seances of columnization, etc., without overcoming the displacement or getting rid of the pain. At the laparotomy it was apparent that the adhesions obliterated the cul-de-sac of Douglas and that the massage had simply elongated the adhesions, producing a mobility of the organ and no more. The operation consisted merely in tearing away the adhesions, freeing the womb and ablating the left appendage which was inflamed. The cul-de-sac of Douglas was also restored. This case shows the probable futility in trying to restore this pouch by massage. When adhesions are extensive the uterus is merely moved until they are rendered long enough to make the pain of traction less, but the cellular tissue is simply elevated into a pointed arch while the obliterated pouch of Douglas is not changed. The retroversion as such is not cured but may be made much less painful.

Goullioud thought that mere displacement of the uterus is not the cause of the pain, so much as the displacements and tractions by adhesions on the appendages.

Jaboulay on July 5th presented a patient who after a traumatism noted a tumor develop in her left breast; after ten months the skin was adherent, invaded, and at the end of last June presented the appearances of threatened ulceration, being red and glossy. The treatment was injections of quinine since the end of the month of June. The tumor had decreased to about one-third its former size, the skin had become loosened and wrinkled and enlargements of the axillary ganglia had disappeared.

Fochier called attention to the fact that a neoplasm at the periphery of the breast is rare, but from the description this one was probably a sarcoma of the skin.

Jaboulay said that the involved axillary nodes argued against sarcoma. Whatever the histology might be the recession of the mass had nevertheless occurred.

Nore-Josserand presented to the society and described a specimen of the pelvis and hip-joints of a child on whom he had operated for congenital dislocation of the hip according to the method of Lorenz four months before it died of pneumonia and at that time exhibited to the Society. Radiographs of the conditions before operation were also at hand. The dissection showed that the muscular insertions were normal but that the muscle bellies were irregularly atrophied. The adductor magnus had been lacerated by the reduction and was the most atrophied. The pelvi-trochanteric group was also very degenerated, while the glutei appeared normal. The articulation showed these features: The socket was quite comparable to the other side; the femoral head had advanced forward considerably; the two capsules were practically nor-

mal as were also the ligaments of Bertin; undue freedom of external, marked restriction of internal rotation were present.

Fochier expressed surprise at the difficulty of diagnosis between infantile paralysis with hip dislocation and congenital dislocation of that joint and asked whether the former disease had been ruled out.

Nore-Josserand said that he had ruled out infantile paralysis on account of the good function during the four months preceding death and of the general condition of the other muscles.

SOCIETY PROCEEDINGS.

NEW YORK STATE MEDICAL ASSOCIATION.

Seventeenth Annual Meeting, Held at the New York Academy of Medicine, New York City, October 15, 16, 17 and 18, 1900.

The first day's session was taken up by the usual business meeting of the Association.

Second Day—October 16th.

Muscular Rheumatism and Electricity.—Dr. James Grant of Ottawa, Canada, was presented to the Association and detailed the results of thirty-five years' experience with muscular rheumatism. He concludes that it is due to the accumulation in the body, not of urea, but of abnormal electricity. This theory is confirmed by success in the treatment of the disease. If ordinary needles are inserted into the rigid muscles affected by lumbago, or pleurodynia or torticollis this abnormal electricity is conducted off and the muscles become pliant and painless. If, when these needles are first inserted, they are connected with a sensitive electrometer the needle is sensibly deflected. On a second insertion after a few minutes no deflection is noted. The needles are left in place only a few minutes.

Nervous and Electric Conductability.—Dr. A. D. Rockwell of New York called attention to the striking analogy that exists between certain electric phenomena and nervous phenomena. Since the announcement of the neuron doctrine, this analogy has become even closer than before. The conditions that make a tube of iron filings a good conductor, though a moment before it was not, are strikingly similar to those which obtain in nervous conduction. As electric conductability is disturbed by untoward conditions, so nervous conduction is disturbed in hysterical states, in paresthesia, in mental confusion, and the like. Certain of these neurotic conditions promptly disappear under electricity. This might be expected from the analogy cited. That which is needed is detailed study of the relations between high-tension and high-frequency electrical fields and abnormal nervous conditions. In electricity is to be found the best agent for the treatment of these trying and obstinate states, and the future is bright for advance in these lines.

Cocainism.—Dr. T. D. Crothers of Hartford, Conn., said that cocaine is now sold freely at drug-stores and grocery-stores and even by tramp pedlars, so that its habitual use is becoming much more common than it was. Dentists, druggists, eye specialists, and throat and nose specialists have been the victims of the habit up to this. Now it is spreading among the lower orders. Habitués, when they cannot obtain it otherwise, steal to get it. When deprived of it in prison they become delirious, even violent. A number of cold and catarrh remedies contain cocaine in such quantities as to be dangerous. In a mill town in Connecticut, where the mill operatives suffer from dust, over 100 people were found to be taking a strong cocaine preparation.

Symptoms of Cocainism.—Many of the symptoms are deceptive. Some of them resemble those of paresis and occasionally such patients find their way to insane asylums. A certain diffuseness of speech is a characteristic of cocaine victims. Clergymen preach too long sermons. Lawyers wander in pleas. Medical professors wander from the point. Hallucinations of persecution especially are frequent. Most cocaine victims carry concealed weapons. The treatment is immediate withdrawal of the cocaine. Bromides often help the symptoms that result. Patients should as a rule be sent away from home for cure.

Points in Heart Diseases.—Dr. James J. Walsh of New York read a paper on some practical points from the discussion on heart diseases at the last International Medical Congress. According to the statements of a number of good observers, valvular lesions of the heart are not so absolutely incurable as they have usually been considered. Petrowich reported a series of cases in which the heart lesion had existed for some time and gave constitutional symptoms as well as physical signs, and yet under a course of small doses of the iodides and precordial applications of the actual cautery the lesions disappeared. The treatment must be kept up for at least a year and in one case it was three years before the cure was complete. Professor Potain said that in young people such a course of treatment should always be carried out and that cures are not infrequent.

Painful Heart Conditions.—For the cardiac discomfort which often accompanies arhythmia a number of observers insisted that, while digitalis very seldom does good and often seems to do positive harm, strophanthus acts very satisfactorily. One of the most prominent of French heart specialists insisted that strophanthus is the ideal heart tonic to use whenever a painful cardiac affection is present. It soothes the pain even though it may fail to correct the disturbed rhythm. While it was agreed that the most prominent cause of heart disease is rheumatism, doubt was expressed as to whether the cardiac lesion is always due directly to the specific cause of the rheumatism or is not still more frequently due to a secondary infection occurring as a com-

plication of the rheumatism. Rheumatic conditions seem to predispose individuals to easy invasion by various micro-organisms. A number of germs have been described as occurring in valvular rheumatic vegetations. Our present knowledge in the matter emphasizes the necessity for the most careful antisepsis of the digestive tract during the course of a rheumatism, for from here secondary infections occur. Tobacco as a factor in the production of heart diseases is attracting more and more attention. A number of cases were reported in excessive smokers in which all the other ordinary causes of heart disease had been carefully excluded. The frank conclusion was that, in susceptible individuals when used to excess, tobacco alone can produce sclerotic conditions in the arteries and heart itself which finally give the physical signs and the functional symptoms of an organic heart lesion. Heredity as a factor in heart diseases also seems to be given more thought than heretofore. Not that direct heredity of an acquired characteristic is presumed, but that a certain lack of vital resistance in the heart seems to be a feature of the physical constitution of certain families.

Symposium on Obstetrics.

Management of the Prepuerperium.—Dr. Edward P. Davis of Philadelphia said that the most important thing to watch during the months immediately preceding labor was the urine. The amount of urine should be carefully noted from time to time, and for this it is well to give the patient explicit instructions that the urine of the whole twenty-four hours shall either be faithfully preserved or carefully measured. It is not sufficient to take the woman's assurance that she is passing as much urine as usual. After the amount of urine, its specific gravity is most important; then the sediment of the urine should be carefully examined. The character of the epithelial contents should be carefully noted and any debris indicating kidney disintegration taken into account. Of course, casts should be carefully looked for. Albumin is only of importance if in very large amounts, or if it is accompanied by other signs of kidney trouble. Blood in the urine is pathogenically significant. When sugar is found, if in the later months, it may be no more than lactose reabsorbed from the milk. In some women glycosuria indicates only a highly neurotic condition and is not pathognomonic of diabetes. It is being realized more and more in recent years that the liver is an important manufactory of many excretory products that afterward appear in the urine. The hepatic condition therefore should be carefully followed.

Diet in Pregnancy.—For the heartburn which is so common a complaint during pregnancy a limitation of the diet is perhaps the best remedy. Milk should be taken in considerable quantities and, if it causes any gastric discomfort, it may be mixed with Vichy or some other carbonated water. As a rule, meat should not be taken more than once a day. It must be borne in mind that coffee and tea check excretion and their use in any quantities during pregnancy should be discouraged. Many a nervous symptom or complaint of pain will disappear if coffee and tea are not taken. On the other hand, there is danger in limiting the diet too much, for the woman's strength must be thoroughly preserved. Plenty of ripe fresh fruit should be taken, and if this cannot be obtained stewed fruit, or preserves not too sweet, or canned fruit. At least one quart of water should be taken a day internally, and, externally a cool sponge bath in the morning and a warm bath at night. For nervous restlessness and insomnia there is nothing more soothing. The pregnant woman should be a great deal in the open air and the house should be well aired.

Drugs.—For symptoms of toxemia salines should be employed—preferably those without potash. Calomel is the best stimulant of excretory processes that we have; 1/20 of a grain may be given night and morning, or 1/100 of a grain three times a day for weeks without producing any mercurial symptoms. Bromides should not be given, because they check eliminative processes and these should rather be encouraged. If hypnotics are necessary, chloral or one of its derivatives is the best. Muscular exercise is of importance. Perhaps the best form of exercise to develop the abdominal muscles is scrubbing on the knees, but from this most of our patients are precluded and walking remains the best general exercise. Compression of the abdomen by a tight bandage or support forces the child down into the pelvis, but weakens the abdominal muscles and sometimes does not give suitable opportunity for the accommodation of the fetal parts to the pelvis. If there is any discharge it should be treated very carefully before labor begins.

Normal Labor.—Dr. Austin Flint, Jr., of New York County said that the most important preparation for labor is to have the patient do considerable walking up to the time labor begins. This softens the lower segment and makes labor much easier. When the doctor is called he should after careful sterilization of the external parts of the woman and of his own hands make an examination that satisfies him as to the exact state of affairs. It is much better to make one good examination than a number of incomplete ones. After this the nurse should be given instructions to see that the patient empties her bladder every hour. An antepartum douche seems according to statistics to do harm rather than good. When the pains become severe, ether should be given in small amounts. This drug seems to be replacing chloroform to a great extent for this purpose. When the first stage of labor is approaching its end it is Dr. Flint's custom to help the dilatation of the cervix by digital manipulation if it seems to be proceeding too slowly. Of course, the bag of waters should be preserved as long as possible, especially in pri-

mipara. Many methods are suggested for the preservation of the perineum. The important thing is to discontinue dilatation by intervals of pressure and then of rest during which a restoration of the circulation takes place. The child's head is the best dilator. If it is being pressed down upon the perineum too rapidly an anesthetic may be employed. The application of the low forceps will help to save many a perineum. If the pains become slow, withdraw the anesthetic and stimulate. For this purpose alcohol should be given, but ergot should never be used. When the forceps are applied, traction should be made intermittently in imitation of Nature's method, so as to permit of a return of the circulation after pressure has been put on the muscles of the perineum. As soon as the head is born the mouth and eyes should be washed out. There is no need to insist upon this precaution with regard to the eyes. With regard to the mouth, however, this practice will be found to save the child many a morbid respiratory condition during the early days of life.

Third Stage of Labor.—The blood should be allowed to escape from the placenta, as this decreases its bulk and permits its expression sooner by the uterus. Any tears that occur in the genital tract should be repaired at once as far as possible. Careful examination of temperature charts of puerperal women will show that the cases in which there is no rise of temperature and no morbid symptoms are those in which there has been no laceration of the genital canal. This is very important, for the infective material growing in tears in the lower genital tract may very well prove the source of contagious material that will invade structures higher up and produce a general septic condition.

After-Treatment of Normal Labor.—Dr. George W. Jarman of New York County said that in women of lax fiber the uterus often presents a tendency to relaxation. Hemorrhage into the cavity of the uterus takes place as a consequence and proves not only weakening, but gives considerable trouble afterward because of the painful expulsion of clots. Where the uterus is not firmly contracted after the delivery of the placenta, the binder should not be put on for half an hour and the uterus should be rubbed through the abdominal wall. It is well to give a dose of ergot immediately after the delivery of the child. If the uterus does not contract firmly after these manipulations a hot intra-uterine injection may be given. The vulva should be kept covered by a rather thick pad of antiseptic cotton. As a rule the binder should be used, partly because of the prejudice in favor of its use as regards the preservation of the figure. The vulval pad should be changed very frequently during the first twelve hours. The child should be allowed to nurse as soon as it and its mother are washed and dressed. The nursing is good for the child and acts reflexly on the mother to produce a firm contraction of the uterus. Even in perfectly normal cases there will be sometimes a rise of one to two degrees in temperature as the result of the nervous excitement and fatigue. If the urine is slow to come, hot cloths should be placed on the abdomen. If necessary, a sterile glass catheter should be employed and the nurse should be instructed to pass it by sight under due precautions. After the third day the woman should be allowed to sit up in bed to urinate. In case nervous excitement causes insomnia sodium bromide may be used as a sedative. Until the bowels have been freely moved a liquid diet should be exclusively employed. If the bowels are not moved freely of themselves, a gentle laxative should be given from forty-eight to sixty hours after the labor. As good as any is the time-honored castor oil. It is to be remembered that coffee will lessen the milk secretion if it is excessive. If all women understood that mammary abscesses are not the result of cold or of caking, but always come from fissures of the nipples, much more care would be taken of the nipples and there would be many less mammary abscesses. The woman should be taught to lie on her side as much as possible as this more surely protects her from retroversion of the uterus. As to getting up it is not a question of days, but of conditions. As a rule after seven to eight days, if the patient is well, she may sit up in bed. A day or two later, when there is lochial discharge, she may be allowed to get up into a chair. If the red flow returns she must be put back to bed at once and must not be allowed to get up again for two or three days.

The Newborn Child.—Dr. Bernard Cohen of Erie County said that as soon as a child is born it should be placed on its right side in order to favor the closure of the foramen ovale. Its face should be turned from the vulva to avoid any gush of fluid, and it should not be placed too far away, in order to avoid traction on the cord. The cord should not be ligated at once, but as much as possible of the placental blood should be allowed to find its way into the child's circulation. If but a short stump of cord is left less material is present to dry up and there is less danger from manipulation. The mouth of the child should be cleansed with a piece of soft sterile rag on a clean finger. In dressing the child a tight band should not be put on. After the cord has dropped it would be well not to use the usual belly-band. It is supposed to prevent umbilical hernia, but in reality it favors it by weakening the abdominal muscles. Many nurses have the custom of giving the baby a little warm water in sugar. This serves as a gentle laxative and is as good as anything else until the mother is able to nurse. For constipation after nursing has begun water and sugar may prove laxative, or a little manna may be administered.

Ophthalmia Neonatorum.—Dr. John Weeks of New York County said that at times the infection of ophthalmia seems to be antepartum. When the first symptoms become manifest more than three days after the labor, it is practically certain that the infection has come from a source other

than the genital tract of the mother. At times, of course, the ophthalmia of the newborn is due to anomalies of the tear sac. Usually if the symptoms develop before the fourth day the infection is due to the gonococcus of Neisser, no matter how mild the symptoms are. Cases that develop later are not due to the gonococcus. Knowing as we do now how long gonococci may persist in males and also in females, it is very easy to understand how gonococci may be present in the genital tract of the female long after the father or mother has had an acute attack of gonorrhea. The other microbes that occur on the conjunctiva of the newborn are the pneumococcus, the bacillus of acute conjunctivitis and the Klebs-Löffler bacillus. According to the statistics of the American Ophthalmological Society, out of 50,000 blind in the asylums of this country 5000 owe their misfortune to ophthalmia neonatorum.

Prophylaxis.—Statistics show that prophylactic precautions will reduce the number of cases of ophthalmia very materially. Out of 17,500 newborn children in various maternity hospitals in New York where no prophylactic precautions had been taken about 9 per cent. developed some ophthalmia. Credé at Dresden demonstrated that in 12,000 cases treated by his method, that is, by the instillation of a drop of a two-per-cent. nitrate of silver solution immediately after birth, less than 1 per cent. developed ophthalmia. Others have suggested washing out the eyes of the newborn with a dilute sublimate solution or carbolic acid solution, or with sterile water. None of these agents have given nearly as much satisfaction as the nitrate of silver. This measure may be employed immediately after the child's bath and should always be employed if there is the slightest suspicion of an abnormal discharge, however slight, in the mother. When the disease develops attendants should be warned at once of its contagiousness. The other eye should be protected by frequent cleansing. Protective shields give no satisfaction in infants. The reason why any conjunctival condition in a child is apt to become severe is that there is very little lacrimal fluid and hence the pathological material is not washed off. This gives the primary indication for treatment, frequent cleansing of the eye. The second indication is found in the biology of the gonococcus. This germ as well as the microbe of acute conjunctivitis does not grow well at a temperature lower than 92° nor above 110° F. It is not easy to raise the temperature of the eye, but it is comparatively easy to lower it to 90° F. and so prevent the luxuriant growth of the bacteria. The prognosis in any given case depends on the general health of the child. Healthy children's eyes can be saved even when very bad.

Major Obstetrical Operations.—Dr. Edward Reynolds of Boston said that version and high forceps for contracted pelvis give practically no more mortality for the mother, but a mortality of 50 per cent. for the child. Induced labor has about the same statistics, about 50 per cent. of the children dying before they reach the age they would have attained had they been born at full term. The Cesarean operation has a mortality of from 35 to 40 per cent. Unfavorable cases, that is, women who are exhausted by having been days in labor, are much more unfavorable while favorable cases have a rather low mortality. With the Cesarean operation the child is nearly always saved. In symphysiotomy the mortality is only slightly larger in unfavorable than in favorable cases. This is easily explained because there is practically no shock. The fetal mortality in symphysiotomy is not very low, however. The principles that must guide the general practitioner, according to Dr. Reynolds' experience in 22 successful cases where major operations were necessary, are as follows: Use forceps or version if possible; if not then the Cesarean operation is better than prematurely induced labor if it can be applied in favorable cases. In unfavorable cases symphysiotomy must be the operation of choice if the mechanical conditions in the pelvis will permit it. If the mechanical conditions will not permit it, then the child's head must be crushed. It is better to save the potential mother of many children, rather than to sacrifice her for her unborn fetus. In order to secure most cases under favorable conditions, the woman's condition must be discovered before labor. Whenever a primipara is abnormally small in stature, or suffers from any deformity of the hips or legs, the general practitioner should call in a consultant if he does not feel equal to pelvimetry.

Puerperal Sepsis.—Dr. William R. Pryor of New York County said that sepsis is due in only a very small proportion of cases to autoinfection. It is known that forty-nine per cent. of prostitutes and a certain number of maritally-infected women have persistent foci of gonococci in the glands of their cervix. These may suffer from self-infection. Certain pregnant women have purulent foci in their tubes. But these very rarely cause puerperal sepsis, because they produce either sterility or give rise to early abortions. Most of the infection comes from without. The only scientific method of treating puerperal sepsis is to examine the secretions carefully in order to find their bacterial contents. This secretion must be obtained, not at the vulvar orifice, but from the cul-de-sac of the vagina through a sterile tube. In about one-third of the cases the infection will be found to be due to streptococci. In a certain number of cases pyogenic cocci will be found, while in most cases only saprophytes occur. Intermittent washing has been used on general principles for all cases of puerperal sepsis. In the pyogenic and streptococcic forms it will be found to do very little good. Saprophytic infection will at once begin to improve under this treatment. Marmorek's serum will be found to do very little good even in cases of streptococcic origin. It is now known that there are many varieties of streptococci and

one cannot be sure which variety is present nor can one be certain of having the antitoxic serum for that special variety.

Treatment of Puerperal Sepsis.—For septic thrombosis the removal of the uterus often does good. This is the only form of puerperal sepsis in which hysterectomy is ever indicated. For other forms of sepsis Dr. Pryor has tried with very satisfactory results this method: The uterus is first thoroughly curetted and then Douglas' pouch is opened and iodoform gauze is packed tightly around the uterus. In a few hours iodine will be found in the urine and this seems to have a good effect on the toxins in the blood. If the pulse rises to 120, three quarts of normal salt solution are injected intravenously. By this many seemingly hopeless cases can be saved.

Symposium on the Blood.

Points in Technic.—Dr. Edward K. Dunham of New York County detailed the technic of blood examination, dwelling especially on certain less frequently used methods of investigating blood composition which have come to notice in recent years and which promise to be of service for the clinician. With regard to the taking of specimens Dr. Dunham insists especially on the most scrupulous cleanliness. Cover-glasses or slides should be washed in water, in bichromate of potash solution, in sulphuric acid and in alcohol and ether. Only thus can all dirt and grease be removed from them.

Specific Gravity.—To determine the specific gravity of the blood a drop of it is placed in a mixture of chloroform and benzol. If the drop of blood floats on the surface of this mixture its specific gravity is higher than it and benzol is added until the blood sinks. If it goes to the bottom then chloroform is added until in either case the drop of blood eventually floats freely in the chloroform-benzol mixture. When it does so, it is of the same specific gravity as the mixture, and this is determined by an ordinary h drometer. Usually at the beginning of the observation the chloroform-benzol fluid is taken of the ordinary specific gravity of normal blood. The reason for this special mixture is that the blood remains entirely coherent in these fluids, that is, it is not dissolved or diffused in the mixture, but floats as a more or less spherical body. This determination requires absolutely no apparatus, but takes considerable manipulation and some practical familiarity with the method or a good deal of time is consumed. Specific gravity may be determined by direct weighing. For this a capillary-tube is filled first with water, then weighed very exactly on a delicate balance; then carefully cleansed and dried, refilled with blood and again weighed. Comparison of the two weights gives a ratio from which the specific gravity of the blood can be easily decided. The method is very simple, but it requires an accurate balance weighing to one-tenth of a milligram.

Reaction of the Blood.—This is often thought to be of special significance. Its determination is not difficult, but it requires very delicate reagents. Usually a solution of tartaric acid is added to the blood until it is just neutralized. The point of neutralization is determined by very delicate litmus paper. To do this exactly requires familiarity with the use of the chemical reagents for such determinations.

Rapidity of Coagulation.—In recent years it has often been thought desirable to know the rapidity with which the blood coagulates. Certain points in prognosis, especially in gall-bladder operations when patients have suffered for a long time from severe jaundice, are said to be dependent on the coagulability of the blood. It may be determined rather easily as follows. A capillary-tube is taken, the lumen of which is something less than 1 25 of an inch. In this some blood is allowed to flow and then a clean white horsehair is passed through the column of blood in the tube. As long as the horsehair on being removed from contact with the blood remains colorless, no coagulation has taken place. As soon as the blood clots it becomes covered with a red color.

Hemoglobinometry.—Dr. Dunham showed the instruments of Gowers, Fleischel, Oliver and Baer. He stated that these determinations of the hemoglobin by means of comparison of colors are open to several sources of error. One is that diffusion of the coloring matter of the blood does not always take place in the same length of time. When the observation is made this diffusion is often not complete and the reading of the amount of hemoglobin is necessarily lower than it should be. Baer attempted to remove this source of error by making his color comparison with the undiluted blood. Another source of error is the personal equation in the appreciation of tint agreement. This amounts to at least five per cent.

The Ferrometer.—Hemoglobinometric methods are open to certain seemingly inevitable objections and the attempt is being made to obviate them by determining, not the color of the blood, but the amount of iron in it. The iron present represents very nearly the amount of hemoglobin. Some of the metal, it is true, is dissolved in the plasma, but this is not enough absolutely to vitiate ferrometric conclusions. To determine the amount of iron the blood is evaporated, the residue incinerated and the fused ash dissolved in bisulphate of potash solution. To this a sulphocyanide is added so that a ferrocyanide is formed. This gives a distinct color to the solution, which is then compared with a solution of ferrocyanide of known strength.

Leucocytosis in Surgery.—Dr. Joseph C. Bloodgood of Johns Hopkins University said that the presence of leucocytosis in acute abdominal surgery can be of the greatest service by enabling the surgeon to make a definite diagnosis a few hours earlier than would be otherwise possible. As hours are precious in abdominal surgery this promises to be a valuable aid in the near future. In three conditions especially is the determination

of the presence or absence of a leucocytosis important: They are appendicitis, peritonitis, and intestinal obstruction. In acute purulent conditions leucocytosis rapidly ascends. Even in simple non-purulent so-called catarrhal appendicitis there is distinct though not very marked leucocytosis. In gangrenous appendicitis, or where the appendix is distended with pus, the leucocytosis rises rapidly.

Peritonitis.—At the onset of the peritonitis there is an immediate rise in the leucocytosis. This becomes very high when the peritonitis is of a virulent character. Very often after perforation of the intestine there is rapid fall in the number of leucocytes. If the leucocytosis continues high for the first 36 hours, it is of no special significance in the prognosis. If, after 36 hours, the leucocytosis persists, the prognosis is good and nature is going to triumph over the infection. In cases that are to be fatal there is a drop in the leucocytosis after 36 hours.

Intestinal Obstruction.—Cabot of Boston asserted some time ago that in intestinal obstruction there is no rise in the number of leucocytes. Leucocytosis has usually been found in these cases at Johns Hopkins. In obstruction with gangrene the leucocytosis rises very high. The higher the leucocytosis the shorter time it takes to rise. Further details of this paper will appear later in the MEDICAL NEWS.

Pernicious Anemia.—This paper was read by Dr. Alfred Stengel of the University of Pennsylvania (see p. 603).

Leukemia.—Dr. C. Y. White of the University of Pennsylvania said that leukemia is a form of anemia characterized by the presence of a very large number of white blood-cells and a reduced number of red blood-cells. All the forms of white cells in the blood are increased in number, but not all of them equally. This gives rise to certain types of leukemia. Two special forms of cells have been described as occurring in leukemia—the neutrophilic myelocytes and eosinophilic myelocytes. The presence of these cells, however, is not pathognomonic of leukemia, for they have been found in other blood disturbances and in certain infectious fevers. The study of the microscopic character of the blood has led to a division of leukemia into two types, *viz.*, the spleno-myelogenous and the lymphatic forms of the disease. Spleno-myelogenous leukemia is really a pernicious anemia with an increase of the white cells and the presence in considerable numbers of the neutrophilic and eosinophilic myelocytes. Lymphatic leukemia presents less degeneration of the red blood-cells and less disturbance of the normal form of the white cells and of the proportion between the different forms of white cells existing in normal blood. In a word there is less disturbance of the blood-making organs. It is evident that further study of the minute characters of the white blood-cells will enable us to draw more definite conclusions as to the course of cases of leukemia and their ultimate prognosis.

Treatment.—Practically the only remedy that has done good in certain cases of leukemia is arsenic. It should be given in increasing doses as the tolerance of the patient will permit and should be continued for long periods of time, but with interruptions in order to avoid the production of complications that sometimes follow the arsenic treatment. It seems worth while noting that in two cases of leukemia in which abdominal operations were done there was for a time after the operation a reversion to the normal number of leucocytes in the blood.

Parasites in the Blood.—Dr. Leon T. LeWald of New York County read a paper with this title. He pointed out and illustrated the distinctions between the germs *Culex*, non-malarious and *Anophcles*, the malarial carrier. This paper will appear in a future issue of the MEDICAL NEWS.

Blood Examination in Trichinosis.—Dr. H. C. Gordinier of Rensselaer County read a paper on this subject. It is only within recent years that the value of a differential blood-count has been recognized. A great increase in the eosinophile cells is characteristic of this condition. This paper will appear in a future issue of the MEDICAL NEWS.

THIRD DAY—OCTOBER 17TH.

Address by Dr. Charles A. L. Reed.—It affords me extreme pleasure, as President of the American Medical Association, to acknowledge your cordial greeting. I recognize and accept it as an expression of filial devotion to the National organization, which, for the time being, I have the honor to represent. My pleasure is intensified, however, because I find in your charter, a copy of which has been placed in my hands by your efficient Secretary, a declaration of objects or principles which appeal to me with peculiar force. They are more comprehensive than those usually embraced in the fundamental laws of medical associations. The first two that are enumerated—the advancement of our humane sciences and the maintenance of honor and character in our ranks—are themselves sufficient to commend this organization to the good favor of every practitioner in this Empire State. The third, providing as it does for the beneficent protection of brethren who have fallen in the great strife, must touch a sympathetic chord in the bosom of every physician who appreciates the mutability of fortune. In no calling of life may misfortune come more swiftly, more relentlessly, than in that devoted to the welfare of humanity. It is the irony of experience that often he who most needs succor is the Samaritan himself. Your example, therefore, in this regard, is worthy of emulation by every State medical association in the country.

I am, however, on this occasion particularly interested in the fourth plank of your platform. I allude to that statement which declares that one of your objects is the establishment of harmonious relations, as the charter itself declares,

"the establishment and furtherance of cordial professional relations and fellowship between the medical profession of the State of New York and the medical profession of other States of the United States and of foreign countries through the medical associations and societies of such States and countries."

Criticism of that declaration must exhaust itself in commendation. In it are embodied what should be recognized as the essential elements of medical organization throughout the profession. It is a hopeful sign that such a broad catholic principle should have been enacted into law by the legislature of a great State, and should have been voluntarily subscribed to by the vigorous, progressive and enlightened men assembled in this hall. I like to think of all that is implied by this part of your splendid organic laws. It breathes the spirit of harmony. It means, if it means anything, and it does mean, as it should mean, the union of the medical profession of New York. It means, as it should mean, that every member of this organization should become a member of the American Medical Association—and I am gratified to know that many already sustain that relation. And finally, it means, as it should mean, that, over and above all, you stand consecrated to the union and the solidarity of our great National profession. Your initiative will meet with a hearty response, not only from the American Medical Association, but from the great independent body of the profession. The genius of harmony, of unity, of fraternity, is abroad in our ranks. It will brook no opposition. Yet this movement is not revolutionary; it is, rather, the culmination of another stage in the resistless evolution of our profession. It ought, therefore, to take but little time and less effort in which to make a change which, in sentiment, is already accomplished. There is but little necessity, the country over, for rescinding resolutions, altering by-laws or amending constitutions, although some memories may well be effaced and possibly some conventions, that have honorably served their day, but that are now relatively meaningless, may well be either modified or revoked. He who interposes either prejudice, preference or prerogative as obstacles to this consummation must be recognized and treated as the enemy of progress. Organization, and organization, too, in the direction of union, must advance. The dissemination of science, the advancement of professional standards, the maintenance of a wholesome *esprit de corps*, the promotion of benevolent enterprise, and the increase of the power of the profession at Albany, at other State capitals and at Washington, all depend upon it. This, and more, is clearly implied by your splendid declaration of purpose, and I come to tell you that the profession of the entire country is with you. I am convinced, and I have reasons for my conviction, that the profession, acting through its organized bodies, is ready and anxious to take steps that will enable it to present a united front to the dawning century.

Diphtheria and Milk Supply.—Dr. Chauncey P. Biggs of Tompkins County gave some details of twenty-eight epidemics of diphtheria the origin of which had been traced to the milk supply. Of these ten followed the distribution of milk that had been handled by some one connected with a family in which diphtheria existed. Eighteen epidemics were reported in which the source of infection seemed to be the existence of chapped teats and ulcerated mammæ in the cow. In England, according to Dr. Lennox Browne, diphtheria of the lacteal structures in the cow is called chapping. In the District of Columbia three milk epidemics of diphtheria were traced in which a dairy-maid, a dealer, and a milk-wagon driver were affected by diphtheria. From Germantown an epidemic is reported in families of good sanitary surroundings who had no intercourse with one another and whose only community of interest was the same milkman. In such epidemics the milk-drinkers in a family are the only ones attacked originally. Members of families who drink only boiled milk escape.

Diphtheria in Small Towns.—Prof. Veranus A. Moore of Cornell University showed that the spread of diphtheria can only be prevented by quarantine carefully maintained until the bacterial examination of the throats of those who were affected have been negative in three consecutive cultures. For this a bacterial station is absolutely necessary. It is not difficult, however, in a country district to have such a station in some centrally-located town to which the cultures can be sent for examination. These culture methods make it possible to trace the course of epidemics of diphtheria and also to find their origins. Such data will soon enable us to limit very much the spread of diphtheria. Prof. Moore has found that the bacilli of the disease remained in throats on an average of fourteen to twenty days. The longest time after an attack that virulent diphtheria bacilli were found in the throat was fifty-three days.

Tonsils as Portals of Infection.—Dr. Julius Ullman of Erie County said that in recent years we have come to realize more and more that the tonsils are the gateway for many infections. The connection between affections of the tonsils and rheumatism and various forms of endocarditis was pointed out. The constant presence of many pathogenic germs in the mouth gives a very favorable opportunity for the invasion of bacteria whenever a reduction in resistive vitality occurs. The frequency with which chancres of the tonsil occurs shows how liable to infection are the open mouths of the tonsillar crypts. All types of cocci have been found in the tonsils and there is no doubt that many forms of tonsillitis are not only infectious but contagious. Many sore throats are followed by nephritis and it seems probable that many an insidious Bright's disease that makes its appearance suddenly in later life is the result of a sore throat in early years.

The Throat Rheumatism.—Dr. Jas. J. Walsh of New York County in the discussion said that,

while rheumatism is now generally conceded to be an infectious disease, its specific cause is unknown. It is known, however, that rheumatism predisposes its victim to secondary infection by other bacilli. To these rather than to the rheumatism itself many rheumatic complications are due. Even the heart disease is now often attributed to this. The secondary infective bacteria find their way in through the digestive tract and not infrequently through the tonsils. There is need, therefore, that the mouth should be frequently cleansed.

Diphtheria and Pneumonia.—Dr. Delancey Rochester of Erie County described a case in which sore throat found to be of diphtheritic character was accompanied by the symptoms of bronchitis. The diphtheria grew better under antitoxin. The pulmonary condition developed and a typical case of pneumonia ran its course. Another case was of an almost similar character. They illustrate the necessity for employing all means of physical examination wherever suspicious accessory symptoms suggest that the diagnosis is incomplete.

Scarlatina.—Dr. Delancey Rochester described three cases in the children of one family during the course of an epidemic of scarlatina. None of them presented any rash, but there was the typical disturbance of pulse-respiration ratio. In a warm bath the skin reddened very easily. All of the children desquamated after several weeks. These cases show how easy it is to miss slight cases of scarlet fever and so permit spread of the disease. During epidemics all febriculæ in children should be suspected.

Jonnesco's Operation.—Dr. Marcel Hartwig of Erie County reviewed the status of the neurectomy of the cervical sympathetic which has been popularized by Prof. Jonnesco of Bucharest. It has now been used for a number of different pathological conditions. Jonnesco himself operated in 97 cases of severe epilepsy, 15 of which were improved. In exophthalmic goiter 15 cases have been operated on, one of them unilaterally followed by unilateral improvement. Of the 14 remaining cases 10 were cured and 4 improved. In glaucoma the operation has given particularly good satisfaction. It is best adapted to those cases in which iridectomy does no good. It is followed by improvement of vision even where iridectomy has failed to bring improvement. Thus far 12 patients have been operated on for glaucoma and in no case has the operation failed to give improvement while in some the effect has been marvelous. Operations for the removal of the cervical sympathetic have now been done for over five years. In no case have the dreaded physiological consequences that so many anticipated been observed.

Climate in Tuberculosis.—Dr. Clarence G. Campbell of New York County said that in the present enthusiasm for sanatoria for the tuberculous it was sometimes lost sight of that climate is the most important factor in the successful treatment of tuberculosis. Patients whose circumstances permit will find their surest benefit in a region where air and sunlight and freedom from germs make the conditions most suitable for health. Such a climate is Arizona, where sunshine is abundant, where irritating dust particles carrying bacteria are infrequent, and where at low altitudes conditions of dryness obtain that can be secured at similar altitudes nowhere else. This tract of low-lying valleys of great dryness is the characteristic climatic condition that makes Arizona suitable for consumptives. The temperature of many parts of the State is too warm in the summer months, but then patients can change their habitations to go farther North. A yearly change of this kind always does good in any climate.

President's Address.—Dr. E. D. Ferguson of Rensselaer County then delivered the presidential address, the subject of which was umbilical hernia. During the year he has had occasion to operate on several large umbilical hernias. He found that the ordinary method of reducing the sac and then bringing the edges of the umbilical opening together, in the hope of making a radical cure, was often a failure, because too much tension was exerted on the stitches in bringing the sides of the opening together and it was impossible to secure firm union. By large hernia he does not mean any particular size, but refers to those in which, after the contents of the hernial sac are reduced, it is very difficult or impossible to bring the edges of the hernial ring in apposition. Having to operate on one of these cases, he found that there were tissues lying alongside the umbilical ring which he could use as flaps to cover the opening. He made an incision, about five inches long, at the outer edge of each rectus muscle, the middle of the incision being at the umbilicus. This incision cut through only the outer sheath of the rectus muscle. Transverse incisions were then made and the sheath lifted up from the muscle. This gave two flaps of aponeurotic tissues which could easily be united in the midline by shoemaker's sutures. These flaps, being attached normally where the circulation is rather good, gave very healthy tissue thoroughly capable of bearing the strain that might be put upon them by internal abdominal pressure. Several months after the operation Dr. Ferguson noticed a slight tendency to relaxation of tissues at the lower part of the apposition of the flaps. It is here particularly that a series of transverse interrupted sutures must be carefully put in in such a way as to be secure and yet avoid strangling the tissues. The skin was incised once more and these sutures were put. The case has since been doing very well. During the second operation an excellent opportunity was afforded to examine the flaps and the state of union. Every thing was found firm and solid.

Symposium on Tuberculosis.

General Etiology.—Prof. Victor C. Vaughan of the University of Michigan said that it is now generally conceded that tuberculosis is always due to the tubercle bacillus which was described

by Koch about twenty years ago. Certain questions of etiology, however, still remain open. The bacillus tuberculosis is known to be parasitic in animals, but there is a doubt as to whether it might not occasionally be saprophytic, that is, capable of living on dead material. At first the morphology of the tubercle bacillus was considered to be that of a simple rod. Branched forms of the bacillus have, however, been found and in a series of cases it has been known to assume a form similar to that of the ray fungus. At first these branched and radiate forms were thought to be degenerate types of the organism, but they have been found to occur even when injections are made intra-arterially, indicating that they are forms with very special vitality. An opinion has been growing of late that the tubercle bacillus is really a type of a higher fungus. A number of bacilli have been found that resemble it. A pseudo-tubercle bacillus has been particularly described which occurs very frequently in butter and which cannot be distinguished except by inoculation experiments. A bacillus that has all the staining characteristics of the tubercle bacillus occurs in timothy hay. This bacillus is, however, not pathogenic for man, or at least only very slightly so, and the lesions that it produces do not resemble those produced by the tubercle bacillus. It has therefore been assumed that the tubercle bacillus is a pleomorphous fungus at times pathogenic, at times not; at times saprophytic, at times only parasitic. The conversion of the non-pathogenic form into pathogenic varieties has been looked for, but has not yet been found. It is probable, however, that the tubercle bacillus we know is only parasitic. It may have certain relatives, like the pseudotubercle bacillus or the timothy bacillus, that belong to the same family, but are never convertible into it. After all, edible and poisonous mushrooms belong to the same general order of plants, and yet no botanist claims that any innocent form ever by any chance becomes poisonous.

Animal Tuberculosis.—Animal tuberculosis occurs only where the disease can be contracted from other animals that have the affection. More than this, it is contagious only when the tissues are broken down and the animals are casting off the infective material. Tubercle bacilli never exist in expired air, unless little droplets of mucus or saliva are coughed or sneezed up. As is known it is acquired by transference from animal to animal. A number of epidemics have occurred as a consequence of circumcision. Tuberculosis frequently invades tattoo marks from infected saliva. In a number of cases surgeons have inoculated themselves during operations upon tuberculous subjects. These unconscious experiments are as convincing as experimental inoculation in animals.

Prophylaxis.—It is known that the tubercle bacilli may pass through the intestinal walls without producing a lesion at the point of penetration and thus give rise to tuberculosis in many parts of the body. Because tubercle bacilli may get into the circulation it is necessary to exercise the greatest care with regard to tuberculous milk and meat. Every dairy cow should be tested by tuberculin and every dairyman should have a license. Non-tuberculous cows alone should be allowed to furnish milk for human consumption. It is to be remembered that the bacillus of bovine tuberculosis is more virulent for animals than is the bacillus found in the sputum of man. The virulence of the sputum bacillus can be increased by being grown in milk. In general, however, there seem to be marked variations in the virulence of the bacilli that affect individuals. Dr. Vaughan has seen a most rapidly-fatal case of phthisis florida develop in a magnificent specimen of young manhood two months after he began to live with a tuberculous mistress. There is, of course, in addition a difference in the susceptibility of different individuals and this varies in the same individual. Of the regular soldiers who went to Santiago not one probably had active tuberculosis. Yet within three months fourteen died of tuberculosis and a number developed the disease in its most active form. The conditions surrounding the tuberculous patient are important in this respect. While fifteen in 10,000 die in Hamburg from tuberculosis who are worth more than $500, forty die in every 10,000 of those who are worth less than $500. In order to eradicate tuberculosis the important first step is to improve the condition of the city poor.

Tuberculosis of Nose and Throat.—This paper was read by Dr. Jonathan Wright of Kings County. It will appear in a subsequent issue of the MEDICAL NEWS.

Ocular Tuberculosis.—Dr. Charles Steadman Bull of New York County said that tuberculosis of the eye is very rare. It occurs mainly as a secondary infection in individuals suffering from tuberculosis in some other part of the body. On the conjunctiva it is even more rare than on other structures in the eye and does not occur more than once in about 30,000 cases of affections of the conjunctiva. It occurs oftener in children, although in them the iris and choroid are affected oftener than the conjunctiva. Tuberculous infection of the conjunctiva is nearly always situated on the inner side of the upper lid and occurs only where some lesion of that membrane already exists. The lid is swollen and edematous and when everted a punched-out ulcer, with a greyish base or with grey nodules resembling miliary tubercles, is found. At times this bleeds easily on handling. Usually the pre-auricular gland is enlarged, sometimes also the submaxillary gland. Bacilli may be found in scrapings. They are hard to find, as a rule, in sections made from tissue excised in the neighborhood of the ulcer. It is not an unusual thing for the affection to be bilateral. The differential diagnosis involves trachoma, epithelioma and syphilis of the conjunctiva. In trachoma the main differential factor is the absence of bacilli. Epithelioma is diagnosticated by the age of the patient

and by the glands being involved late. The diagnosis of syphilis is made by the greater acuity of the process and by the therapeutic test. The treatment of tuberculous conjunctivitis consists in the excision of the ulcer, if it is near the margin of the lid, with a plastic operation to fill up the defect, or thorough cauterization of the ulcer if it is at a distance from the edge of the lid.

Corneal and Retinal Tuberculosis.—Tuberculosis of the cornea is very rare. In strumous children, however, it is always well to suspect a persistent ulcer of the cornea as tuberculous. The treatment of these conditions is much more constitutional than local. Tubercles on the choroid do not occur as often as is thought. They are said to be frequent in meningitis and in general tuberculosis, but they are very rarely discovered during life as they exist mostly in young children in whom the difficulty of examination is very great. Tubercles in the retina and optic nerve occur as the result of the extension of the tuberculous process from the meninges. Gauze-like opacity covering the optic papilla is often noted. A picture not unlike this occurs in syphilis, however, but usually marked symptoms of meningitis have been noticed before the tubercles in the eyeground are found. Where tubercles can be seen in the eye the differential diagnosis of typhoid fever from general tuberculosis is clear.

Auricular Tuberculosis.—Dr. Seymour of New York County said that tuberculosis of the ear is usually secondary to pulmonary tuberculosis. Tubercles occur not infrequently on the tympanum, but often run so latent a course that their presence is not noted until a discharge occurs. From the tympanum the infection passes through the drain of small bones into the internal ear and causes a chronic pathological process. Such affections develop only in anemic, debilitated patients. There is undoubtedly a communication of tuberculosis from the throat through the Eustachian tube to the ear in tuberculous patients. The prophylaxis of auricular tuberculosis requires the most careful management of laryngeal tubercle. Patients should be warned not to attempt to perform the Valsalva experiment, because tuberculous material may easily be forced into the Eustachian tube. For a similar reason the use of the Politzer bag for simple salpingitis should be avoided. There is no doubt that many patients have had infective material forced into the Eustachian tube by thoughtless inflation.

Treatment of Auricular Tuberculosis.—Constitutional treatment of patients affected by tuberculosis in any other of the structures of the ear is much more important than the local treatment. A progressive obstinate lesion may be arrested by a stay in the Adirondacks. If operations are to be done, an especially nourishing diet with tonic treatment should be given for several weeks before the operation. Granulations in the ear should be kept down by the use of the snare or by cauterization with chromic acid. Lactic acid has given such good results in laryngeal tuberculosis that it deserves a trial in auricular cases also.

Peritoneal Tuberculous Glands.—Dr. Maurice H. Richardson of Harvard University said that very few operations have as yet been done for tuberculosis of the glands of the peritoneum. However, there are circumstances under which operation not only relieves the patient of a painful condition, but probably saves life. Of late, since operation on the abdomen has become much more frequent, it has been found that enlarged glands occur in the mesentery much oftener than was thought. The symptoms of severe cases are abdominal pain, fever and tenderness. They resemble very much the symptoms of appendicitis. Usually, when the symptoms occur, the glands are already broken down and there may be an abscess in either iliac fossa. At times ascites occurs, but only in very advanced cases. The treatment of the condition is the opening of the abdomen and drainage. At times the symptoms from these enlarged glands are so severe as to indicate an acute trouble. Any of the glands in the mesentery may be affected and sometimes extensive operations are required for their removal. In the cases reported thus far, however, the glands have all been caseated and have shelled out rather easily. Large amounts of broken-down tissue can be thus removed without much risk. At times the removal of large portions of the mesentery may endanger the life of a portion of the intestine by disturbing its circulation. If this occurs it can be noticed rather easily after a few minutes by the darkened color of the intestine. When such a complication occurs a portion of the intestine must be excised. One risk involved in the operation is that the free anastomosis at the base of the mesentery may threaten serious hemorrhage, which, however, may be controlled by packing.

Urinary and Uro-Genital Tuberculosis.—Dr. Samuel Alexander of New York County then read this paper, which appears in this week's issue of the MEDICAL NEWS. (See p. 599.)

Bone and Joint Tuberculosis.—Dr. E. H. Nichols of Boston described the pathology of tuberculous bone lesions and illustrated by lantern slides the original focus in the epiphyseal cartilages and its gradual advance into the true bony substance with disorganization of joint structures. In Pott's disease the illustration showed the beginning of a tuberculous process in the bodies of the vertebræ and its gradual advance to the surface beneath the spinal ligaments. A very striking illustration shows that notwithstanding pronounced deformity the spinal canal remains absolutely unencroached upon by the tuberculous process. Nervous symptoms occur in Pott's disease either as the result of a subdural abscess, or of pressure on nerve-roots because of the development of the tuberculous processes around the spinal foramina. At times a sort of dislocation takes place because of the softening of the bodies of the vertebræ and then the upper fragment may press upon the cord. Dr. Nichols

illustrated how extraordinary extortion of the aorta may be as a consequence of the spinal deformity. In these patients, usually adults, the aorta, having reached its full development, has to accommodate itself to the shortened spinal column. In the treatment of certain cases of joint disease, it must be remembered that when conditions have become inveterate the circulatory system gradually accommodates itself to the altered state of affairs. If a misguided effort is made to restore former conditions as far as is possible with the deformity, the manipulation may cause interference with the blood supply. Dr. Nichols showed a case in which there had been ankylosis of the knee-joint with backward dislocation. In improving the position of the knee this backward dislocation was not corrected although the limb was straightened. The result was interference with the popliteal artery. The foot became gangrenous and had to be amputated. Later on amputation had to be done above the knee.

Cutaneous Tuberculosis.—Dr. John A. Fordyce of New York County read a paper on certain phases of tuberculosis of the skin and the superficial fascia. Although many other forms of cutaneous tuberculosis have been discovered in recent years, lupus presents such a distinctive picture with special features of its own that it still deserves a separate place. That it is surely tuberculous is known from the fact that at times generalized tuberculosis results from the scraping of a lupus patch. Besnier of Paris condemns this method of treating lupus for this reason. Epithelioma occurs so often in the scars of old lupus that there is no doubt that something more than chance causes it. The devitalized tissues of the tuberculous lesion seem to make an especially favorable nidus for its growth and its prognosis is much more grave.

Other Tuberculides.—Dr. Fordyce showed a series of other lesions of superficial tuberculosis. An interesting condition is lymphangitis, a tuberculous process following very closely a set of lymph-vessels. Other illustrations showed a series of glandular lesions in which only the lymph-glands had become infected and then, after caseation, broke down. All tuberculous skin affections are much more common in the young than in adults. Seventy-five per cent. of patients who suffer from lupus acquire the affection before they are twenty.

Differential Diagnosis.—Certain cutaneous lesions resembling those produced by the tubercle bacillus have been described in recent years. Of these the most prominent is blastomycetic dermatitis, caused by organisms which closely resemble the yeast. The most important affection that presents itself for differentiation is cutaneous syphilis. Dr. Fordyce presented a picture of a case in which most hideous deformity of the face had taken place in consequence of what was thought to be a tuberculous process. The therapeutic test showed that it was syphilis. The lesions healed in a few weeks under proper treatment. Unfortunately, however, irreparable damage had been done to the tissues of the eyes and the nose.

Fourth Day—Thursday, October 18th.

Ichthyosis Hystrix.—Dr. Frederick Holme Wiggin read for Dr. George W. Goler of Monroe County a paper on the treatment by electric light of this usually obstinate affection. The case was one of congenital ichthyosis in which the arms from the lower third to the shoulder and beyond the axilla were covered by a series of brownish, roughened protuberances resembling flat warts. On the legs the affection extended from the malleoli up to the trunk, and patches existed on the abdomen and flanks. The cheeks and auricles were also scaly. The patient was subjected to electric light. Lanolin was rubbed into the arms and then the light, a twenty-ampere lamp, was concentrated on the affected parts by means of two eight-inch plano-convex lenses. After two seances of twenty minutes each the arms were much improved. After twenty days, with eighteen half-hour exposures to the light, the cure seemed complete. For the legs the arc light was used and its rays were concentrated by a nine-inch parabolic reflector. For three months the patient has remained perfectly well. During the summer he perspired freely from the affected patches. He has never perspired before from these areas. The severity of the case shows that this was one of the forms of true ichthyosis hystrix of which Hyde says, "In no case can a favorable result be anticipated." Notwithstanding this unfavorable dictum this case seems to have been completely cured.

Specific Corporeal Gravity.—Dr. Heinrich Stern of New York County reported a series of investigations upon the specific gravity of the body and upon the value of this factor in physical diagnosis. He has found that the human body in health varies in its specific gravity from about 1060 to 1075. Patients whose specific gravity is lower than 1060 are always delicate in health and usually have some serious organic disease. On the other hand, individuals whose specific gravity exceeds 1075 are apt to have some serious disturbance of nutrition or defect of metabolism. The subject is only just opening up, but it seems to promise to be of decided value in the differential diagnosis of neurotic conditions from true organic disease or from serious disturbances of metabolism. It is not unlikely that further developments may show that more explicit information can be obtained by this method of testing the corporeal specific gravity.

Aseptic Minor Surgery.—Dr. Douglas Ayres of Montgomery County said that now that asepsis has become so thoroughly established as the rational basic surgical principle, even the minor operations done in the practitioner's office must be performed as far as possible with every aseptic precaution. It is well worth the trouble it entails in the lessened worry over morbidity after operation. In addition the practitioner owes it

to himself and to his patients to do his surgery in the best possible manner.

Intestinal Obstruction by Meckel's Diverticulum.—Dr. John F. Erdmann of New York County gave the details of three cases of this anómalous character that have come to him for operation in the last six months. The condition, obstruction by the anomalous persistent diverticulum, is very rare, yet these three cases by that peculiar chance that always sends anomalies in series have been encountered in his private practice in so short a time. Ths symptoms of the condition resemble very much those of appendicitis. In the first case it was thought that acute appendicitis might be at the bottom of the symptoms. The incision for the condition was made the same as if for an appendicitis operation. The diverticulum was treated just as the appendix would be if it were the offending agent. If it was small, it was inverted into the intestine; if it was large, it was simply amputated and sewed up as if it were intestine. All three of the cases recovered without incident and have continued in good health ever since.

Ectopic Gestation.—Dr. Hiram N. Vineberg of New York County dwelt on the difficulty of making an assured diagnosis of this condition in many cases. Where the classical symptoms are present there is very little difficulty. Time is an important factor if the safety of the patient is to be assured. Whenever what seems uterine abortion, but with any suspicious symptom, occurs Dr. Vineberg suggests that an examination under an anesthetic should be made. This is the only method that will assure against the unexpected in these serious cases. This as a routine practice would save many lives. The difficulty so far with regard to these cases has been that the physician is put off his guard by the seeming simplicity of the conditions that obtain when he is first called to the patient.

Modern Minor Gynecology.—Dr. H. H. Goelet of New York County said that the resources of modern minor gynecology are too little valued by the general practitioner. In diagnosis the use of the microscope has rendered the possibility of more rational treatment much easier than before. Endoscopy of many body cavities has become a feature of modern diagnosis. Uterine endoscopy may give important information. Dr. Goelet exhibited a uterine endoscope that has proved itself of great service. In therapeutics the use of uterine irrigation promises to be of great value. Dr. Goelet presented a uterine irrigator which requires no dilatation of the cervix for its use and can consequently be employed in every-day office work. Electricity, though its employment has been decried, the benefit derived being set down to suggestion, has proved itself of too great practical value in too many hands to be so lightly dismissed. It must always be remembered that many gynecological symptoms either depend on or are aggravated by lack of nervous tone and the presence of constipation. For the first the gold and arsenic preparations will be found to give brilliant results where many other things have failed. For chronic constipation the old Pharmacopœia cathartic pill, every third night, is better than most of the new-fangled remedies and it need not be increased to produce its effect.

Intraspinal Cocainization.—Dr. S. Ormand Goldan of New York County detailed some recent experience with this method of producing local anesthesia. A brilliant future seems to be opening up for this new adjuvant to painless surgery. There are certain disadvantages attached to the procedure as yet which may disappear as the technic improves. As it is some of the disadvantages that attach to general anesthesia are not completely done away with by this latest method, though it was hoped and promised that they would be. At times the shock of the operation and perhaps toxic symptoms from the cocaine produce an analogous post-operative condition in the patient to that familiar to us as the usual after-effects of ether or chloroform. On the whole, however, this new method is a distinct addition to our medical and surgical means of relieving human suffering and of extending without danger to certain classes of patients, as those suffering from heart and kidney trouble, all the benefit of the great advances in modern operative surgery.

Election of Officers.—The following officers were elected for the coming year: President, John A. Wyeth, New York County; Vice-President, Alvin A. Hubbell, Erie County; Secretary, Frederick Holme Wiggin, New York County; Treasurer, E. H. Squibb, Brooklyn; District Presidents, 1st, Charles B. Tefft, Oneida County; 2d, John T. Wheeler, Columbia County; 3d, Theron A. Wales, Chemung County; 4th, William H. Thornton, Erie County; 5th, J. C. Bierwirth, Kings County.

BOOK REVIEWS.

Manual of Pathology including Bacteriology, the Technic of Postmortems and Methods of Pathologic Research. By W. M. Late Coplin, M.D., Professor of Pathology and Bacteriology, Jefferson Medical College, Philadelphia; Pathologist to Jefferson Medical College Hospital and to the Philadelphia (Blockley) Hospital; Bacteriologist to the Pennsylvania State Board of Health. Third Edition, Revised and Enlarged. 8vo., 846 pages. Philadelphia: P. Blakiston's Son & Co. $3.50 net.

Research activity in every avenue of medicine brings forth so many results that each year witnesses some important shifting in mental attitude in one or another of the great problems of medical science. So constant is this striving for newer outlooks that the text of to-day on the morrow often becomes the history of a more primitive conception. Perhaps in no single department is this so apparent as in pathology,

where the labors of thousands are ever contributing their wealth of new knowledge. With these conditions it is no facile matter or light responsibility to be the author of a work on pathology. However, if the worth of a book may in any wise be measured by the appearance of successive editions within a comparatively short time, then Professor Coplin's Manual should rank among the best upon this subject. The present volume follows three years after the publication of the second edition.

Notwithstanding the many excellent qualities of the previous edition, considerable revision and addition of new matter have been made in accord with the newer standpoints. Instead of a reprint of the older text the author has conscientiously presented what he considers the best and most recent view-points in pathology. The book has been divided into three parts. The first relates to matters of technic. The chapter on post-mortems has been revised, and the same elaboration of other chapters is also noteworthy. Thus bacteriologic technic has been placed in a section by itself, and the technic of blood-examinations has been transferred to the chapter on the blood where it belongs. In the second part a consideration of general pathological problems is found; this has been enriched by liberal recasting. The remaining 396 pages are devoted to special pathology; and here new chapters have been added on the thymus body, ductless glands, muscles, bones, joints, and nervous system.

In the treatment of the subject the method has been along the traditional lines; the purely objective subordinates the reflective side. This seems unfortunate. A more philosophic presentation would commend the book to the more thoughtful and lead others into the by-ways of higher interpretation of cellular activity. However much we may differ with the general plan and some matters of detail, it must be conceded that this Manual will prove wholly satisfactory to a large class of readers interested in the morphological phases of pathology alone. The mechanical part of the book is good, and the addition of many new illustrations and some colored plates enhance the elucidation of the subject very materially.

Traité de Médecine et de Thérapeutique. Par MM. P. Brouardel, Doyen de la Faculté de Médicine de Paris, et A. Gilbert, Professor agrégé à la Facultié de Médecine de Paris. Tome Septième. Maladies du Nez, du Larynx, de la Trachée, des Bronches et des Poumons. Paris: J. B. Ballière et Fils.

Brouardel's and Gilbert's Traité de Médecine is too well known to need an introduction. As a system it compares very favorably with those of Nothnagel and Allbutt, although not attempting the monographic completeness of the former.

In the present volume of nearly a thousand pages, disease of the nose, the larynx, trachea, bronchi and lungs are considered. The symptomatology of diseases of the lung is very well handled with a clearness and comprehensiveness characteristic of the best French work. The subject of different types of expectoration, the color, tenacity, shape, microscopical and chemical characters, occupies, for instance, some ten to twelve pages, all of which is distinctly practical and bears directly on the diagnosis of the respiratory conditions. The chapter on pneumonia by L. Landouzy is a very able presentation. Twenty pages are devoted to treatment. Grancher and Barbier have given a monograph on tuberculosis which compares favorably with those of Strauss and Cornet.

As a system this represents the best work of the French school, a school which is, we believe, being overlooked by many in their eager rush for voluminous German monographs.

Injuries to the Eye in Their Medico-Legal Aspect. By S. Baudry, M.D., Professor in the Faculty of Medicine, University of Lille, France. Translated by Alfred James Ostheimer, Jr., M.D. Revised and Edited by Charles A. Oliver, A.M., M.D. With an adaptation to the United States by Charles Sinkler, Esq., Member of the Philadelphia Bar. The F. A. Davis Company, Philadelphia, New York, Chicago, 1900.

It is well known how often injuries of the eye occur in the industries and manufactures. As they often give rise to dimness of vision or sometimes to complete blindness and so become the subjects of damage suits, the value of this little book will be thoroughly appreciated. The translation is excellently done and the editorial revision has been thorough. The fact that Dr. Oliver thought it worth reproduction in English is of itself an assurance that the book is thoroughly practical.

The Medical Diseases of Childhood. By Nathan Oppenheim, A.B., M.D., Attending Physician to the Children's Department of Mt. Sinai Hospital. 8vo., 653 pages. Illustrated. New York and London: The Macmillan Company.

The author of the Development of the Child, already reviewed in our columns, has tried something more ambitious in this present volume. He has, moreover, given the medical profession something new in the way of a text-book which cannot fail of commendation. The old-fashioned dry statistical mode of presentation has been cast aside and a book with a more narrative and descriptive text is given which in many ways is to be commended. From the pedagogic side we believe the book disappointing. The author has omitted many of the clinical features and substituted histo-pathologic details. The point of view is certainly open to discussion, but the recognition of the external features of a disease process is certainly more important than a knowledge of minute post-mortem alterations. Even these are faultily presented by microphotographs which, as a type of illustration, we be-

lieve are a great mistake. They no doubt are attractive to the taker who has seen the originals and unconsciously fills in the details by suggestion, but for the outsider we consider them for the most part worthless. The book we believe lacks balance. The rarest and most peculiar diseases, while of great scientific interest, are dilated on, especially their pathology, to the detriment of the more common ills of childhood. This being said, however, it is not meant to convey the idea that this feature derogates very largely from the value of the book as a whole. It is really an excellent exposition of the general subject of medical diseases of children. The work from the standpoint of the bookmaker's art is all that could be desired.

Transactions of the American Dermatological Association. Twenty-Third Annual Meeting. Official report by George Thomas Jackson, M.D., Secretary. Concord: The Rumford Press, 1900.

Although poor paper and a paper binding give a cheap appearance to this book, its contents are furnished by some of the leading skin specialists. M. B. Hartzell reports cases with areas of keratosis on the palms, soles, back and abdomen, believed to be due to arsenic, and in which epitheliomata subsequently developed. L. D. Bulkley gives a study of the urinary excretion in eczema, acne, pruritus, and other skin diseases. No special urinary changes appear to have direct connection with any particular skin lesions, but the findings indicate that there are errors in nutrition and metabolism which affect the skin. J. T. Bowen describes two epidemics of alopecia areata in a girl's school; S. Sherwell contributes on congenital dermatitis herpetiformis, and on the treatment of scabies. Several articles follow on macular leprides, infection in leprosy, indurated erythema with necrotic granuloma, epidermolysis bullosa, etc. Geo. T. Elliott opens a general discussion on "The Rôle of Pus Organisms in the Production of Skin Diseases," by an exhaustive tabulation of the pus-producing germs, and the pustular diseases. He separates the affections in which pus is an essential factor from those in which pus is merely secondary, such as scabies, pustular eczema, pustular syphilis, etc. T. C. Gilchrist makes a study of vesicular and pustular skin lesions, and describes a new branching organism, the bacillus (?) acnes, as the most frequent germ found in the pustules of acne vulgaris. Each paper is thoroughly discussed by the other members, and a number of photographic illustrations add to the value of the work.

BOOKS RECEIVED.

Operative and Practical Surgery. For the use of Students and Practitioners. By Dr. Thomas Carwardine. 8vo., 661 pages. Illustrated. John Wright & Co., Bristol.

Manual of Pathology. Including Bacteriology, the Technic of Postmortems, and Methods of Pathologic Research. By Dr. W. M. Late Coplin. Third Edition, Revised and Enlarged. 8vo., 846 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia. $3.50.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Dr. H. A. Hare, assisted by C. A. Holden. Vol. III. September, 1900. Diseases of Thorax and its Viscera, Skin and the Nervous System, and Obstetrics. 8vo., 408 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York.

A Treatise on Mental Diseases. Based on the Lecture Course at Johns Hopkins University, 1899, and Designed for the Use of Practitioners and Students of Medicine. By Dr. H. J. Berkley. 8vo., 601 pages. Illustrated. D. Appleton & Company., New York.

A Treatise on Diseases of the Nose and Throat. By Dr. Ernest L. Shurly. 8vo., 744 pages. Illustrated. D. Appleton & Company, New York.

Brain in Relation to Mind. By Dr. J. Sanderson Christison. Demi 8vo., 143 pages. Illustrated. The Meng Publishing Co., Chicago.

Psychopathia Sexualis. With Especial Reference to Antipathic Sexual Instinct. A Medico-forensic Study. By Dr. R. v. Krafft-Ebing. 8vo., 586 pages. W. T. Keener & Co., Chicago. $5.00.

A Manual of Otology. By Dr. Gorham Bacon. Second Edition. Illustrated. Demi 8vo., 422 pages. Lea Brothers & Co., New York and Philadelphia. $2.25.

Transactions of the Louisiana State Medical Society. Twenty-first Annual Session, 1900. 8vo., 427 pages.

A Dictionary of Medical Science. By Dr. Robley Dunglison. Twenty-second Edition. 8vo., 1376 pages. Lea Brothers & Co., Philadelphia and New York. $7.00.

The Art of Breathing as the Basis of Tone-Production. By Leo Kofler. Fifth Revised Edition. Demi 8vo., 278 pages. Illustrated. E. S. Werner Publishing and Supply Co., New York.

Speech-Hesitation. By E. J. Ellery Thorpe. Demi 8vo., 75 pages. Edgar S. Werner Publishing and Supply Co., New York.

An Inquiry into the Conditions Relating to the Water Supply of the City of New York. By the Merchants' Association of New York. 8vo., 627 pages. Illustrated.

Original Contributions Concerning the Glandular Structures Appertaining to the Human Eye and Its Appendages. 8vo., 23 pages. Illustrated. American Journal of Ophthalmology, St. Louis, Mo. $1.50.

Practical Uranalysis and Urinary Diagnosis. A Manual for the Use of Physicians, Surgeons and Students. By Dr. Charles W. Purdy. 8vo., 406 pages. Illustrated. F. A. Davis Company, Philadelphia, New York, Chicago. $3.00.

Sixth Otological Congress, London. Transactions edited by E. Cresswell Baber. 8vo., 477 pages. Illustrated. The Southern Publishing Company, London.

Seventh Annual Report upon the Births, Marriages, Divorces and Deaths in the State of Maine for the Year Ending December 31, 1898. Augusta, 1900.

Medical Directory of New York, New Jersey and Connecticut, 1900. Published by the New York State Medical Association.

Manual of Diseases of the Eye. For Students and General Practitioners. By Dr. Charles H. May. Demi 8vo., 406 pages. Illustrated. William Wood & Company. New York.

ORIGINAL ARTICLES.

THE CITY AND ITS CONSUMPTIVE POOR: A PLEA FOR A MUNICIPAL SANATORIUM OUTSIDE OF THE CORPORATE LIMITS.[1]

BY ALFRED MEYER, M.D.,

OF NEW YORK.

IT is just one year since I had the honor of addressing you upon the subject of the State care of the consumptive poor, and of pointing out to you the worthy example of Massachusetts that had been so splendid a pioneer in this work and in this country. Since then, those interested in the welfare of this unfortunate and neglected class of patients have had abundant cause for rejoicing in that the State of New York was finally induced at the last session of the legislature to commit itself to the principle of State aid by the appropriation of $50,000 for a State sanatorium. The commission appointed by the Governor to select a site has worked hard and conscientiously during the summer. Twenty-six available sites at widely-distant points in the Adirondacks were inspected and quite recently a decision was finally made in favor of Lake Clear. In spite of delay caused by the opposition which has developed against this site, there is a strong probability that within the next eighteen months the State of New York will have reared its first sanatorium for the cure of incipient tuberculosis, and, by so doing, will have increased very greatly the probability of similar institutions in every State of the Union, and both directly and indirectly strengthened the forces that are arrayed against this disease.

It is not generally known, even to members of the medical profession, that the first organized effort for a separate city institution for consumptive poor dates back to 1855, when a society, with Peter Cooper as president and Dr. Alonzo Clark and other well-known citizens as trustees, was chartered by the State and issued "An Appeal to the Inhabitants of the City and State of New York." The arguments used were almost identical with the ones used to-day.

(1) Humanitarian—"The hospital is found a truthful exponent of the Christian sentiment of the people."

(2) Inadequacy of the then existing provision—"For the victim of consumption there is no suitable refuge whatever, but, had the existing institutions abundant room for and were they in a position to receive all the cases of consumption which might apply, still there would remain the serious objection that they are not properly adapted to this purpose; that they cannot supply those means and appliances requisite for the satisfactory and enlightened treatment of this disease."

(3) Immensity of the problem, consumption taking the first rank as an agent of death, and removing the subject mainly in a productive period of life.

(4) Value of light, air, exercise, and diet, and the hopelessness of obtaining these for many cases in the "narrow confines of the dwellings ordinarily inhabited by them."

(5) Improved opportunity for studying the disease scientifically among large numbers, and thus eliminating the chance causes.

(6) Existence of such special hospitals in England.

From the charter we learn further that the hospital was to be established within ten or fifteen miles of New York City and that it was to have power to hold real and personal estate to an amount not exceeding $250,000. To these arguments of forty-five years ago the modern advocates of municipal aid have been able to add a number of others, all more or less related. Among these are: (1) The earlier recognition of the disease by bacteriological methods; (2) the greater hopefulness of arresting its progress; (3) the danger of infection.

The subject to which I invite your attention this evening is closely related to that discussed last year. There is this important difference however: Then, the object was to enlarge the State's responsibility for the indigent consumptive; my object to-night is to urge the need of greater responsibility on the part of the City. Under the law of 1899 this certainly appears justifiable from a medical point of view. Permit me to quote from the law: "Any municipal corporation, having a population, according to the last State census, of 250,000 or more inhabitants, shall have the power, whenever its Board of Health shall deem it necessary for the promotion of the health of its inhabitants, to establish, equip and maintain, outside of its corporate limits, and at such place or places within the State of New York and not within the corporate limits of any other municipal corporation, as may be determined upon under the provisions of this Act, a hospital or hospitals for the regular treatment of the disease known as pulmonary tuberculosis."

No one, certainly no medical man, will deny the advantage to the incipient consumptive if the City should avail itself of the authority granted by this law to acquire suitable territory outside

[1] Read before the Section on Medicine of the New York Academy of Medicine, October 23, 1900.

of its corporate limits and to send the patient there for treatment instead of sending him to the public institutions within the city. In certain quarters a notion has prevailed that no steps were taken under the law of 1899 because of a supposed conflict of authority between the Department of Charities and the Department of Health, or rather because the law placed the selection of the site and the construction and equipment of the hospital in the hands of the Department of Health in place of the Department of Public Charities. Nothing is further from the truth. The Department of Health stands ready to assume the labor and responsibility connected with the work, while the Department of Charities both admits the need of the work and its acquiescence in the law as it now stands. In the course of the discussion this evening, you will, I believe, hear a confirmation of this statement in the personal evidence of officers of these two departments. In fact, both departments are thoroughly imbued with the importance of the subject, and while they deplore the vastness of the problem they also admit the incalculable benefit that would accrue to the healthy and the sick alike by an extension of the work along the lines indicated in the title of my paper.

The main obstacle to action under this law has been the fear of expense. The bugaboo of expense. There is a certain immortality in this argument that would almost lead one to believe it were possessed of a soul—but there never was a more soulless argument. Still it is forever bobbing up to obstruct improvements and reforms, and, though it has been knocked in the head hundreds of times in the past and in connection with other matters affecting the welfare of the municipality and its citizens, it reappears with the serenity and the dignity and the glory of a newborn thought, but with a doggedness worthy of a better cause.

What would we think of a man who would advocate to-day a return to the old system of a volunteer fire department in the place of our present paid force, merely because it was cheaper and satisfied the needs of a smaller city and a smaller civilization? We have expanded municipally since the days when every ten-year-old lad "ran with his engine"—we have expanded in territory, in population, in the progressiveness of our ideas, but also expanded in our municipal pocketbook. The question to be asked is not, What will it cost? But, Will it pay for its cost? Permit me to quote from a recent article in the *Wiener klinische Rundschau*, written by the director of the Sanatorium at Alland, near Vienna. He says: "The great expense connected therewith, which appears to be the main argument against the establishment of municipal sanatoria, must appear in an entirely different light to every one who studies the facts—that is, to every one who studies what it costs society to support the consumptive until he dies, and what it would have cost had he been cured or at least sufficiently improved by treatment according to modern methods to permit him to return to the ranks of bread winners."

To sum up, we are spending enormous sums to-day, often without the saving of even a life, merely because it is being spent at the wrong time. Our motto should be, as was so forcibly expressed by Dr. Pryor last year: "At the right time, in the right place, in the right way, until cured; not, at the wrong time, in the wrong place, and in the wrong way until dead." I had hoped to have the City's chief financial officer discuss this matter from the point of view of the economical public servant bound by his sense of duty and by his oath of office to protect the treasury from extravagant and frivolous outlay. It was my desire that this Section should learn directly from him the financial outlays to which the City was already committed, the true status of the City in relation to the legal debt limit and the extent of the support or opposition that those interested in this movement might expect from the Department of Finance. I said to him: "You may pitch into us if you choose—but let's know at least where you stand and, if need be, let's have it out." I obtained a definite promise from him to attend this meeting, but no positive promise to take part in the discussion. I sincerely trust we may hear from him.

But let us suppose that we have allayed the fears of our opponents regarding the total of the original outlay; and let us suppose they are satisfied to allow us two or three hundred thousand dollars for this purpose—they will still fear the demand for fabulous millions in the future, to care for *all* the incipient cases, and they shudder at the thought of saddling the City with this enormous burden. Now, how much approximately would it cost the City if it were to embark upon a project of this kind? According to the Board of Health reports, there were in Greater New York during the current year, up to and including September 22d, 6079 deaths from pulmonary tuberculosis, from which we can deduce a death-rate for the year 1900 of about 8100. If we remember that the death-rate and the average duration of the disease remain about the same, we are forced to the conclusion that there are about 8100 new incipient cases each year, taking the place of those who have died. If each one of the 8100 had six months' sanatorium treatment the expense would be equivalent to the care of one-half that number for one year, or about 4000 cases. At the most liberal estimate nine-tenths of these may be classified as poor and liable to become a public charge; this reduces the total to 3645. If we allow for those taken care of by private charitable agencies the number is further reduced to about 3000, for whom buildings and equipments would cost about $3,000,000, and annual maintenance about $1,000,000. But no one has asked that this burden be assumed by the City. An appropriation of about $300,000 is all that the friends of this measure are asking for, and those who persist in claiming that this sum is but the beginning of

an endless chain of annual appropriations should recall the fact that in the future the City will be the judge of the practical value of its first investment.

The claim is made that the proposed measure will not eradicate the disease. Is this a reasonable objection? Because we may not be able to eradicate the disease, shall nothing further be done toward limiting its spread and toward diminishing its death-rate? This philosophy of sitting down and waiting for the millennium to come, this philosophy of wanting to do nothing because you cannot do everything, will in my humble judgment scarcely appeal to a people as practical as the American people. It seems very much like wanting to treat nobody because you cannot save everybody—a doctrine which surely my colleagues of the medical profession will be slow to accept; otherwise, since they cannot eradicate death, they might as well give up the practice of medicine and go to teaching music or to farming, if you please. We may be justified in being conservative, but this is not conservatism; it is pessimism of the rankest kind, and pessimism, as Dr. Van Dyke very justly says, "never gets anywhere. It is a poor wagon that starts with creaking and groaning."

Some fear the opening of City institutions for a multiplicity of disease. For instance: Why not a City hospital for cancer? And if not, why not? I should answer that cancer is not so prevalent as pulmonary tuberculosis, that provision for its care is not so inadequate, and, most important of all, that cancer has not been proven to be communicable and therefore is not a menace to a healthy citizen.

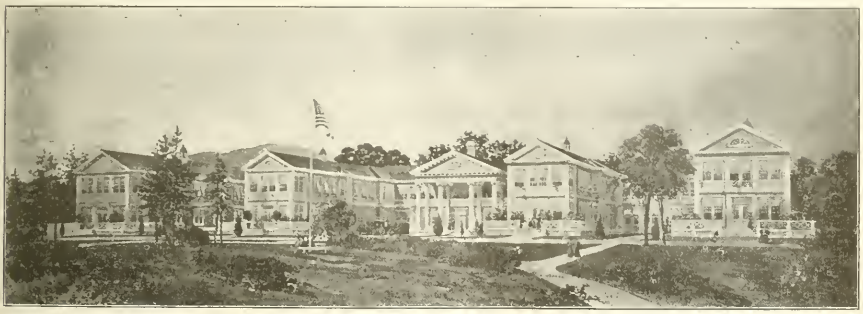
Some may raise the cry of excessive paternalism and the paralyzing of individual effort, as they did against the movement for State care. In reply I may state that in the very midst of this agitation for public aid, the directors of the Montefiore Home of this city—private citizens, mind you—in place of waiting for action on the part of the city, have planned and pushed to completion at Bedford Station, Westchester County, a sanatorium, where 160 incipient consumptives can be cared for in accordance with modern methods. While we have that type of philanthropists among us, we need have no fear that the hand of private charity will be palsied.

Having answered the objections allow me to tabulate a few cogent reasons why, in my opinion, the proposed hospital should be established.

(1) The problem is an enormous one and requires the union of all forces, municipal, State and private.

(2) There is no doubt that the expressed sentiment of the profession in this city is in favor of the plan. Let me remind you that in November, 1899, the President of the State Board of Health sent a copy of the bill under which I am advocating action to 5000 physicians in New York and Brooklyn, and that out of 1512 answers received (which large number in itself was evidence of unusual interest) there were 1500 answers in favor of and 12 opposed to action being taken. A more striking endorsement of a public measure has rarely, if ever, been reported.

(3) The increased hopefulness of the medical profession of the curability of the disease. For proof of this, I need only point to the results of sanatorium treatment coming to us from all parts of the world, and to the establishment of sanatoria by German Invalid Insurance Companies, as a life- and money-saving measure. The results in Germany have been so favorable and have stimulated the erection of sanatoria to such a degree that about 20,000 incipient cases can now receive treatment for three months each, and 72 per cent. of these are returning to the ranks of wage-earners (Pannwitz, *Berlin. klin. Woch.*, No. 30, 1900).



Country Sanatorium of the Montefiore Home for Incipient Tuberculosis at Bedford Station, Westchester Co., N. Y.

(4) The inadequacy of public and private endeavor. Under this head let me offer the following evidence:

With 8000 annual deaths from consumption in Greater New York, we may fairly deduce that the total number of consumptives living in all stages at any one time reaches 25,000, and probably the number is nearer 30,000. A census of all the cases of phthisis in all the hospitals, public and private, in Manhattan and The Bronx,

taken on January 20, 1899, showed only 1010. A study of the figures from the boroughs of Brooklyn and Queens may increase the total by about 100.

Manhattan and the Bronx.			
Census of Tuberculosis cases in Hospitals, January 20, 1899.....			1,010
New cases	548		
Cases previously reported.....	462		
Tuberculosis cases reported by Institutions to the Department of Health during year 1899.....			10,178
Bellevue Hospital	1,008		
Bellevue Dispensary	433		
Metropolitan Hospital	907		
City Hospital	308		
Harlem Hospital & Dispensary....	57		
Gouverneur Hospital & Dispensary.	191		
Total		2,904	
Duplicates, or of this number there had been previously reported....	867		
Other institutions, physicians' cases and sputum examinations..		7,274	10,178
Duplicates	1,605		
Total number of duplicates.....	2,472		
Total number of new cases.....	7,706		
			10,178

In addition a census taken in the Department of Charities, Manhattan and The Bronx, January 1st and October 8, 1900, showed an average of only 250 consumptives, and if we include the cases paid for by the city at Seton Hospital it increases the total number of cases charged to the City to about 365. There are two conclusions to be drawn from these figures: One is that the City is doing insignificantly little, and the other is that private charity is doing twice as much. The figures are even worse than they appear, for a very large proportion of the cases are far advanced in the disease and taken to the hospital to die, *and they should not be allowed to obscure the problem of incipient and hopeful cases*, for whom primarily the out-of-town institution should be established. In proof of this statement I offer the following death-rate among the cases in the Department of Charities, including the Almshouse, Bellevue, City, Fordham, Gouverneur, Harlem, and Metropolitan Hospitals:

Cases of Tuberculosis Treated in Public Institutions in Manhattan, the Bronx and Brooklyn.

Institutions.	*No. remaining Jan. 1, 1900.*	*No. of beds assigned.*	*No. of cases Oct. 8, 1900.*	*No. of cases Jan. 1, 1900, to Oct. 1, 1900.*	*No. died Jan. 1, to Oct. 1, 1900.*

Out of 1839 cases admitted to these institutions from January 1st to October 1st, 1900, there were 635 deaths. Out of 3050 cases admitted to 26 private hospitals in Manhattan, The Bronx and Brooklyn, in 1899, 914 died. In further proof I also offer the following extract from the Fifth Annual Report of the Seton Hospital, 1899: "The great majority of the cases sent by the Board of Health were cases of advanced disease." Let us add to this institutional evidence of the present inadequacy the experience of hundreds of physicians practising in this city, each one of whom is burdened with the care of cases which are hopeful when first seen but become hopeless, because at present the right thing cannot be done by them; let us add the evidence offered by workers in the tenement sections in the city, by the University Settlements, the Charity Organization Society, the United Hebrew Charities, the Association for Improving the Condition of the Poor, some of which organizations frankly admit that they are swamped by these cases, and we are forced to the inevitable conclusion that with all its mercy, with all its generosity, New York has not yet done its full duty.

(5) The disease is a menace to public health. I need not dilate upon this phase of the question before an audience of this character.

(6) An object lesson will be given by New York to those other municipalities in the State to which the same authority has been given, as yet, however, barren of results.

(7) There will be great value in the hygienic education of the patients and their training in the proper distribution of their sputum will diminish the spread of the disease.

(8) The money value to the City of lives saved will be millions of dollars, whether estimated by what it costs to rear and to educate an individual, by what it costs to care for dependent widows and children, or by the law once upon the statute books of this State, valuing a life at $5000

(9) Let me remind the members of this Section that at a general meeting of the Academy of Medicine, held on December 21, 1899, a resolution favoring the establishment of a municipal sanatorium was indorsed. It remains to devise means for furthering this plan, so pregnant with hope for the consumptive poor, and of arousing our public officers into action. In the practice of our profession, than which there is none nobler, the prevention of disease, the prevention of avoidable suffering and its lenghtening chain of misery are among its highest aims. If each one of us in his private, in his public and in his professional life preaches the need of further municipal action, the agitation *will* and *must* bear fruit.[1]

801 Madison Avenue.

REPAIRING THE ABDOMINAL WALL IN VENTRAL HERNIA: A NEW OPERATION.

By CARL BECK, M.D.,
OF NEW YORK.

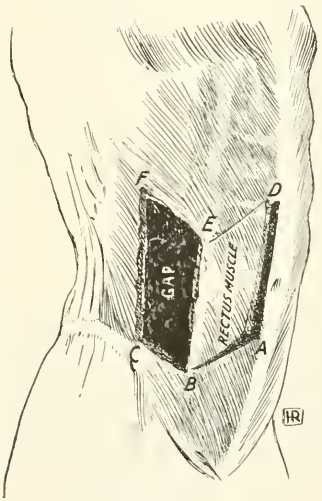
As long as the opponents of early operation in appendicitis are numerous in the profession, hernia as a sequel will continue to be a frequent experience. In an operation too long deferred the large size of the incision, the extensive exposure and the wide packing that are necessary, are quite sufficient causes for the imperfect agglutination of the peritoneum as well as of the muscular and aponeurotic layers of the abdominal wall. Thin connective tissue fills up the hiatus; and as soon as the patient gets up, intra-abdominal pressure produces a hernia.

Sometimes a broad elastic-webbing band with a well-fitting pad may prevent eversion; but in most cases an operation for the repair of the incisional hernia is required. Under ordinary circumstances, and if much time has not elapsed since the operation for appendicitis was performed, excision of the scar, careful exposure of the peritoneal, muscular and aponeurotic layers, and the removal of adhesions between the peritoneum and the underlying intestine, will completely restore the integrity of the abdominal wall; but in complicated cases, and especially when much time has elapsed since the operation for appendicitis, atrophy of the muscular layers having taken place at the same time, the muscular deficiency may be so great that approximation of the muscular layers is out of question.

In such a desperate case I have had to resort to an extensive plastic operation in order to cover the gap. The patient was a man, twenty-three years of age, on whom, four years ago, I had performed an operation for appendicular abscess seven days after the onset of the acute attack. Peritonitis, while not general, still had lost its circumscribed character. The cecum was covered with fibrinous clots which needed extensive exposure and wide packing with iodoform gauze. The patient insisted upon leaving the hospital before the wound was closed completely, and there was no opportunity for seeing him again until three months ago, when he presented himself with a ventral hernia in the scar of the appendicular incision. This caused considerable digestive disturbance. The intestine could be felt immediately below the cicatrized integument to the extent of the palm of a man's hand.

Taking the most minute aseptic precautions, the scar was excised and the peritoneum exposed. After a few adhesions uniting the parietal peritoneum with the cecum were disposed of and the different layers of the abdominal wall were carefully denuded, it was found that an approximation of the muscular tissues was impossible. Muscular tissue was absent; not one fiber could be detected between the margins of the rectus muscle and the anterior superior spine of the ileum. Having ascertained by previous experiments (Medical News, September 16, 1899) how well the rectus muscle tolerates even an extensive loss of substance, I concluded to utilize its superficial layer as a reverted flap for the covering of the gap. For this purpose the rectus muscle was incised alongside its internal margin (Fig. 1, A-D) to the extent of nearly

Fig. 1.



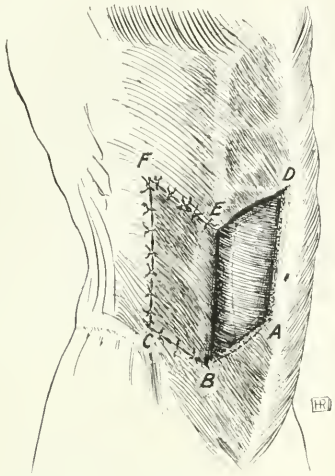
Showing Gap in Muscle.

half its thickness. Two transverse incisions, connecting the outer and inner margins of the muscle (A-B and E-D), and extending down the substance of the muscle to the same extent, the lower one being as near Poupart's ligament as possible, and the other one below the umbilicus, completed the outlining of the flap, which was carefully lifted. Beginning at the internal marking of the incision (A-D), the upper layer of the fibers of the rectus muscle was also divided, until the flap, so formed, could be lifted near the outer margin (B-E) with which it remained con-

[1] See discussion p. 671.

nected in the manner of a hinge. The reverted flap was now fastened to the muscular remnant (Fig. 2, A-C and D-F) with iodoform-silk sutures. The

Fig. 2.



Showing Gap Closed with Flap.

tiers uniting the fascia then consisted of formalin-catgut, which was also selected for the subcutaneous suture. Four relaxation sutures, consisting of iodoform-silk, were applied through the skin three-quarters of an inch distant from the wound-margin, so that there was no direct contact with the wound-line.

Fig. 3.

Showing condition of patient three months after the reversion of the rectus muscles and one month after the operation for hernia.

Recovery was uninterrupted. Where the gap and the attenuated muscular layer were previously established, a thick firm wall could be found. Two months after the operation no protrusion occurred while the intra-abdominal pressure was increased by the efforts of coughing.

Another interesting feature of the case was the coexistence of a congenital inguinal hernia of the same side, for which I performed radical operation (Fig. 3) after the principles emphasized in my modified operation for inguinal hernia (Medical News, September 16, 1899). The patient is now perfectly well.

A PLEA FOR THE MORE FREQUENT AVOIDANCE OF EXSECTION OF THE OVARIES IN CONNECTION WITH OPERATIONS UPON DISEASED TUBES.[1]

By PHILANDER A. HARRIS, M.D.,
of Paterson, N. J.

For the interests of this paper it is convenient for us to regard the uterus as a kind of sinus having attached near its top two additional sinuses, which we call the Fallopian or uterine tubes. When gonorrhea or other disease infects the uterus it is liable to extend to the Fallopian sinuses, and when thus established comfort and health are more or less encroached upon, if, indeed, life is not endangered.

To effect a cure of chronic suppuration in the Fallopian sinuses we have resorted to a variety of exsective and amputative operations. None of them, even the most mutilating, in which the uterus, both tubes and ovaries are sacrificed, can be relied upon to effect a symptomatic cure in every case. The operation most resorted to for suppuration of these sinuses has been the so-called salpingo-oophorectomy by abdominal incision; and inasmuch as both the Fallopian sinuses are generally found diseased, the operator usually sacrifices both tubes and also, as a matter of routine, both ovaries.

Many gynecologists who began as we all did, by removing the ovary with each diseased tube, are still doing so as a matter of routine in every case, and occasionally one is still found who continues to justify his practice in this relation. Others having been convinced that the tubal sinus is the real structure at fault, and that the ovary in a large proportion of cases is only the contiguous and unwilling participant in the suppurative process, have in their later practice confined their ablations to the tube, and have only now and then sacrificed the ovary or ovaries while amputating diseased tubes. I cannot yet say that more than a very small proportion of the gynecologists are removing the Fallopian tubes and leaving the ovaries in most of their cases, but I am entirely convinced that many are doing so and, I am assured, with a fuller measure of satisfaction with their results than were obtained in their earlier and more mutilating operations.

[1] Read before the Section on Gynecology and Obstetrics of the American Medical Association, Atlantic City, N. J., June, 1900.

I wish in this paper to divide all the operations for ablation or removal of the tubes into two general classes and use a term or expression for each class. Class 1 embraces any operation in which more or less of the tube is removed by cutting it off at one point or another between its fimbriæ and the uterus, and I shall refer to any such as an *amputation of the tube*. Class 2 embraces the practically complete removal of the tube which can only be effected by an encircling or elliptic dissection around the tube and into the uterine tissue and a severing of the lumen of the Fallopian sinus at its termination with the uterine mucosa. This incision in the wall of the uterus is then united with close suturing. Such an operation I shall refer to as an *excision of the tube*.

Physiological Functions in Interest.—The continuance of menstruation depends on two conditions; the presence of the uterus, and an ovary or, at least, a portion of an ovary. With these conditions present excision of both tubes neither arrests menstruation nor ovulation, but it, of course, renders pregnancy impossible. The occurrence of pregnancy depends on the presence of an ovary or a piece of an ovary and the uterus, with at least one Fallopian sinus communicating with the cavity of the peritoneum. Pregnancy is possible, and there are repeated instances of its occurrence, through the medium of open Fallopian stumps from which the tubes were amputated close to the uterus. The relative frequency of intra-uterine pregnancy after simple bilateral amputation of the tubes cannot be determined until the practice of removing the ovaries in these cases comes more in vogue. Busy gynecologists who have ceased to sacrifice the ovary while performing bilateral amputations of the tubes, are beginning to report the subsequent occurrence of pregnancy. The small ostium abdominale of a tubal stump, with its unobstructed sinus, is, however, far less liable to receive the ovum and pass it to the uterus than the ostum at the fimbriated extremity of a normal tube.

The complete removal of both ovaries and all ovarian stroma promptly eventuates in the arrest of the functions of menstruation and ovulation. The surgical arrest of the function of menstruation at any age is followed by more or less of the disagreeable nervous phenomena which attend the normal cessation of menstruation at the change of life. The quality of sexual instinct, an item of woman's existence which enters more or less into her life and behavior in various ways, is probably in no way impaired by simple removal of the tubes, but I am thoroughly convinced that removal of the ovaries very often lessens the intensity, while it also often speedily terminates the existence of this quality in women.

With the exception of operations for ovarian tumors, about all of the earlier operations of the uterine appendages consisted in seizing the ovary and tube through the abdominal incision, forming a pedicle in such manner as to secure as much of the diseased tube as possible, and encircling, or transfixing and encircling, the stump thus formed with a ligature, and cutting off the mass on the distal side of the ligature. In all such operations more or less of the uterine end of the tube was left. In some cases a small part of the ovary was unintentionally left. Of the thousands upon thousands of women thus operated on a goodly portion were cured of dysmenorrhea, pelvic pain and general morbidity which rendered life burdensome before operation. Menstruation generally ceased, but in a certain small percentage of cases where ovarian stroma was left, it continued, while pregnancy followed in a very few isolated cases.

Patency of Fallopian Tubes After Amputation.—One would suppose and many have claimed that a tube ligated and amputated on the distal side of the ligature will remain closed. In contradiction to this is the occurrence of pregnancy after bilateral amputation, and the report that in the few patients in whom the stumps have been afterward examined they have been found patent or open. The failure to effect by amputation a symptomatic cure in a certain percentage of cases is doubtless due to the fact that the amputated tube reopens, and that septic exudations continue or recur from subsequent infections. Dr. Bovée has demonstrated with several specimens a condition of open tube-stumps after the ordinary ligature and amputation.

I am strongly inclined to believe that further investigations will demonstrate that a very large proportion of the stumps of tubal amputations either have, or, later acquire an ostium abdominale and an unobstructed, although short, Fallopian sinus to the uterine cavity; and that this contractured yet open sinus is the occasional avenue of stump-infection or reinfection which operators have sometimes characterized as neuralgia of the stump when the patient returned with some of her pre-operative symptoms.

Diseased tubes, as a rule, are recognized readily by the eye, and their removal by amputation eventuates generally in a symptomatic cure. These septic or suppurative processes are usually carried on in the tube and, although they often extend to adjacent parts, particularly the ovaries, the ovaries are unwilling, and in many cases only temporary participants in this suppuration. An ovary with the fimbriæ of a suppurating tube agglutinated to its surface may safely evade infection until a Graafian follicle bursts within its grasp; by which event infection of the ovary and the development of an ovarian abscess is liable to occur.

Although the ovary is often engulfed in exudates, and at times both ovaries are completely covered in, the function of menstruation continues, and, if we dig out and amputate or excise a tube and save the ovary, we also retain for the woman the function of menstruation. If while amputating the tubes we free the ovaries from many of the adhesions which may have hidden them from view, saving them for the woman, they will show little or no disposition to harbor suppuration as do the tubal sinuses which infect

them. In other words, it is the unwilling participant in the suppurations so common in the tube. At a meeting of the American Gynecological Society, in Boston, two years ago, I heard Dr. Howard A. Kelly remark, while discussing the papers of Drs. Dudley and Bovée, as follows: "There is a great deal of talk about chronic ovaritis, but there is nothing in it, for it is a condition which is very rare. Many of us sacrifice the tube or an ovary for purely technical reasons, for it is easier to pull it up and cut it off, as it is usually involved in inflammatory adhesions. We should always make an effort to save the tube or some portion of it, so that the theoretical hope of pregnancy may be retained for the sake of the patient."

Less than three years ago I abandoned the routine practice of removing the ovaries with their diseased tubes. Since that time it has been my custom when ablating diseased tubes to spare to every woman as much ovarian tissue as possible. I can now recall but two instances in which a surgical menopause has followed double tube amputation or excision during this time. I have as large a percentage of cures as was obtained by the coincident sacrifice of the ovaries and I have a grateful class of women, most of whom appreciate the advantages of retaining the function of menstruation. One patient, however, was not entirely satisfied with my having retained for her the function of menstruation and ovulation. During her husband's absence from this country, I amputated both tubes, leaving both ovaries. Six months after the operation, and before her husband's return, she presented herself to me with the appearance of pregnancy. Upon my diagnosis of probable pregnancy, she at once told me that she little thought pregnancy possible to one who had been operated on as she had been; I assured her that it was possible and that I believed her pregnant. Her physician, a man of high standing, who referred her to me for removal of tubes, has since informed me that she had an abortion at about two and a half months, and that it occurred a short time after her visit to me.

This brings to mind the question of how far the patient herself should be consulted in regard to what she should keep or part with when she submits to the knife. The married woman with children, as a rule, does not wish more. The gynecologists, to gratify the wishes of this patient may sacrifice her ovaries, and with it every possible chance of future pregnancy. Her husband dies, she again contemplates matrimony, but she is reminded that she is not a perfect woman, and must make known to the other contracting party her sterility, or possibly afterward suffer the disadvantage of annulment of her marriage contract. For her to make known to the prospectively contracting party her condition of sterility is to lose, in some instances, the re-marriage.

The peculiar social life of some women is such that for the time being they look with favor upon an operation which will sterilize them. There is, however, a certain small percentage of prostitutes who will yet change their lives, marry, and be happy. If for the reason that such cases are but isolated ones, we sacrifice menstruation for the whole class, and with it every possibility of pregnancy, our surgery in this relation may prove a contributing hindrance to their reformation, respectability and happiness.

The woman of respectability, of eighteen, twenty-five, thirty, or even thirty-five, surgically cured of her pelvic disease, but conscious that she is not as other women are, in that she does not menstruate, feels herself personally inferior to womankind, and this feeling of personal inferiority may be so strong in her that it will become a powerfully contributing factor in her general condition of unhappiness. I know of many such instances. Some of them were my patients, operated years ago. I am convinced that sufficient ovarian stroma may be saved to maintain menstruation and ovulation in at least ninety per cent. of all the bilateral tubal amputations and exsections for the so-called purely inflammatory lesions of and primarily in the tubes, and that a cure of the pelvic pains does not depend on the removal of the ovaries, but on a removal of the disease from its pathologically natural habitat, the Fallopian and uterine sinuses. Dysmenorrhea and the pains which precede and follow menstruation, and which are so common in tubal disease, must be particularly inquired into. If these pains had no existence prior to the development of tubal disease, they will probably disappear when the tubal disease is removed and the ovaries need not be sacrificed to effect a symptomatic cure. I have had many cases with post-operative history exemplifying this statement.

In the past, as now, the sick and afflicted relied upon our propositions and accepted our advice. We acted in the light of what we supposed we knew and, while we were praised for our good offices in that relation, we brought the public to believe that almost any kind of a suprapubic section of the female abdomen carried with it the removal of the ovaries and the consequent arrest of menstruation and sterility as a matter of course. The public by instinct, as it were, has wisely resented our invasion of its rights, and I am happy to believe that we can now see our way to effecting as many cures with far less mutilation than in former times, while we can also maintain for almost all these women sufficient of the several and particular qualities to enable them to remain and rank as so-called perfect women.

A woman for whom we have spared sufficient ovarian stroma to continue the phenomena of menstruation and ovulation, but from whom we have exsected one tube and amputated the other, is not very likely to conceive. Still, we cannot say of her that pregnancy is impossible. If we have saved for her the ordinary and outward evidences of the normal functions of woman, and

if for her conception is at all possible, she may rank as technically perfect in womanhood, and without fear of invalidating a contract of marriage should that be made without reference to her past medical history. In view of these facts, for I believe I have presented no claims which cannot be substantiated, we should spare to as many as possible menstruation and ovulation, and also, for whatever it may be worth, the practical although slight hope of conception.

THE IMPORTANCE OF REST IN PULMONARY TUBERCULOSIS.[1]

By CARROLL E. EDSON, A.M., M.D.,
OF DENVER, COLORADO.

With our present understanding of the natural history of pulmonary tuberculosis we must appreciate more and more the necessity not only of early recognition and of securing the largest amount of fresh air and sunshine in its cure, but of the physician having constant and close supervision of all the details of the nutritional and hygienic life of his patient. None of these details can be neglected wisely, but I wish to emphasize especially the importance of securing prolonged rest, for the reason that most patients in the early stages of pulmonary tuberculosis take an amount of active exercise which is liable to do them harm.

In the enthusiasm of securing the greatest abundance of fresh air and sunshine, the error is made of assuming that outdoor life necessarily means walking, riding or bodily activity; and many physicians even advise such exercise in direct conflict with the indications from the pathology of the disease, although they habitually follow the same indications in a case of joint tuberculosis.

The obvious and unquestioned treatment of a case, however incipient, of tuberculosis of the spine or of any joint is the immediate immobilization of the part; the maintenance of complete physiological rest during such time as may be needed for the inflammatory process to subside and the damaged tissue to be walled off. In tuberculosis of the lungs, on the other hand, the local lesion is not thus happily apparent at the start and the disguise of a simple general debility with a little hacking cough leads to forgetfulness of the true pathological state. And yet tuberculosis of the lungs has a natural history, similar to that of a joint infection; the pathological process is in all essentials the same, the microscopical details differing only in the histological structure of the affected tissues.

The indications in each are the same, namely, to secure local tissue rest while the protective changes are secured. The better prognosis of a joint tuberculosis is due in large part to this obviousness of the lesion and to the greater possibility of securing quiet, for a joint can be immobilized while a lung cannot. We need not walk. The maintenance of life necessitates some use of the respiratory apparatus.

Difficulties in the way of complete suspension of function in the lung should not cause us to ignore the indications so clearly shown. The obvious means of physiologically lessening the functional work of the lungs and thorax is to diminish as much as we can the respiratory demands of the body.

Respiration is not simply a thoracic need, but a service called on by all bodily activity. Muscular action directly increases the amount of gas exchange within the tissues and thus augments the respiratory labor. As our respiration is easier when quiet than when running, so it is less when lying at rest than when standing, by just the amount of muscular action needed to hold the body balanced. Pleural friction is less and the quieter thoracic action diminishes cough. This relieves the nervous wear, and protective tissue changes are favored.

Bodily rest is beneficial in other ways than in respiratory quiet, and for similar physiological reasons. The cardiac labor is lessened and the quick, small, irritable pulse of early tuberculosis, which, when continued, is of such evil import, depicts a waste of vital force which were better employed in the local combat against the bacillus.

The most important physiological reason for insisting on rest in pulmonary tuberculosis is the influence of bodily exercise in increasing temperature. As a physiological fact this is known, yet the knowledge is not applied in our rational therapeutics. A most convincing proof of the effect of undue bodily exercise in creating fever is the test made by Dr. J. Bapst Blake of Boston upon the contestants in the Marathon race. In an unpublished paper he says that "the temperature taken by rectum was almost invariably raised. The average rectal temperature was 102.4° F. Omitting two instances in which it was not representative of the true condition, the average rectal temperature at the close of the race was 102.8° F."

Not only our physiological knowledge but our clinical experience shows that the surest way of reducing the fever of pulmonary tuberculosis is by prolonged rest in the fresh air, and by rest I mean as near complete bodily quiet in the recumbent position as can be had. The higher the temperature the more necessary is the complete rest of the reclining position, while a slight afternoon rise is controlled by simply forbidding walking. The harmful effect of cardiac, or indeed muscular or even parenchymatous labor during high temperature needs no elucidation. One avoids it studiously in the fever from pneumonia or typhoid toxins, why call upon it in the fever due to Koch's bacillus?

All our knowledge points to an enforcement of rest in tuberculosis, and our clinical experience also, if we will but read it thoughtfully. All who have had service in a general hospital have seen case after case of phthisis in which the fever

[1] Read before the Section on Practice of Medicine of the American Medical Association, Atlantic City, N. J., June 7, 1900.

and the cough have at once and steadily diminished as a result of the quiet rest in bed and the cessation of nervous exhaustion from labor. I have little hesitation in giving the chief credit to the rest, for too commonly (in the past) the hospital care of chronic phthisis has been a tragic farce. Our clearer vision to-day of pathology and its relation to physiologic life shows us lessons which we were learning without heed.

The importance of rest and the harm of undue exercise during the active stages of the disease are especially apparent in patients coming to a high altitude for the first time. It will be agreed, I feel sure, by all whose work is at a high altitude, such as Denver, that the invalids who keep quiet at the start do best and that immediate exercise is nearly always disastrous. The additional demand on the circulation and respiration made by the thinner air is all the work it proves well to ask at first. If the patient adds to this a further call by muscular exertion—hunting, golfing, riding—the task is over great. Continuance, if not increase of fever, cough and general exhaustion are inevitable. A carefully kept temperature chart of a patient inclined to doubt the effect of exercise in reviving a partly quiescent fever will prove a most graphic argument to him and to his physician for the insistence on absolute quiet.

Let me cite only one case out of many which all can duplicate. G. B., male, thirty-seven years of age, came to Denver in January, 1898, with tuberculous disease of the upper right lung. He had no fever, no cough at night and only a little expectoration by day. His weight was 140 pounds, and his general condition fair, with little impairment of strength. Upon ill-judged advice he took much exercise, fencing for two hours every morning and walking in the afternoon until he was so tired that he had to "will" himself to do it. At the end of four weeks he had lost nine pounds, was coughing a good deal and so much at night as to materially disturb his rest. The pulse was quick and the temperature often 100° F. He looked worn and his face showed the lines of nervous tire. He was ordered to remain in a steamer-chair on the veranda, not leaving it for any reason. In three days his cough at night had stopped, and in three weeks he had gained ten pounds.

The objections usually raised at first to such orders for complete rest are two: First, the mental and moral irksomeness, "I cannot stand it." Experience, however, shows that the patient does stand it very well. I have tried it myself. There is an inertia of action as well as of rest, but with honest trial and kindly device on the physician's part it can be overcome. The second objection is the possible interference with digestion and elimination. This, too, is an unfounded fear. The digestive ability of patients undergoing this quiet during the period of fever and pulmonary activity is astounding at times even to one who is accustomed to it. Two pounds' gain per week for ten weeks is not unusual and I have seen eighteen pounds gained in three weeks without the least disturbance. Any signs of intestinal sloth are more easily remedied than the harm from extension of tuberculous disease induced by overexercise.

The more one sees of the varying picture of tuberculous disease, the more impressed he must become with the importance of giving increasing conscientious attention to every detail of the invalid's life. The amount of exercise, even to the closest measure, must be studied and controlled. As long as there is fever there should be prohibition of exertion. The degree of rest, whether it be continued recumbency or half-day reclining, or simple limitation to a veranda, is a detail for each case, but a detail which should be regulated. The duration of such quiet depends on the results. The more thoroughly it is carried out the sooner the pulse and temperature will become normal. With the cessation of active disease the amount of exercise allowed may be gradually increased, the effects being carefully measured by the temperature, the pulse, the cough, and the weight.

PRESENT STATUS OF INTERSTATE RECIPROCITY CONCERNING LICENSES TO PRACTISE MEDICINE.

By EMIL AMBERG, M.D.,
of Detroit, Michigan.

The medical profession has had the same task since the beginning of civilization. Diseases are practically alike all over the world, and among civilized nations a human life is valued equally high in all countries, or, at least, it should be.

The medical profession, as such, does not participate in the race for national supremacy. The only limit for the standard of the medical profession is the limit of human ability. The quality of the medical profession depends upon the quality of the medical schools. It is an open secret that in the United States the conditions of medical education, in general, are not such as they should be. Whoever is familiar with the literature on the subject will bear me out in my statement. I call attention only to the refusal of diplomas issued by certain medical schools. The only possible excuse for the inability to provide for a medical education worthy of the advanced position the United States takes among other countries, would be economical reasons. Economical reasons, however, fail to excuse the conditions existing at present. Besides this, medical schools belong to the most necessary institutions for the people. Those controlling public affairs should direct their efforts to provide the best possible physicians for those under their care. We all know that the cause of the inefficiency of most of the medical schools can be found in the fact that a few men can get together and, with little difficulty, establish a medical school; and, further, that the diplomas of less good schools are, in the eyes of the public who do not know the difference,

just as good as those of good medical schools. In order to have some kind of control, state or territorial medical boards became a necessity. The more advanced states and territories saw that they were obliged to protect the citizens of their jurisdiction from incompetent practitioners. In this way they put themselves on a higher level than the other parts, and a division takes places which reflects most peculiarly on the weaker states and territories and on the whole country.

What stand does the medical profession take in this question? The very fact that most of our medical schools are private institutions once for all prevents us from identifying the medical profession in the United States with the medical schools, therefore, the medical profession cannot adapt itself to the medical schools; the medical schools, however, must adapt themselves to the demands of the time. It has been a matter of great surprise to me for a long time why the different pathies can get such a strong foothold in the United States. I think that one of the reasons is the following: The inefficient general education, combined with lack of thorough training in physiology and pathology, only too easily induces many physicians to let themselves be controlled by the deplorable tendency to give too many drugs. It is reported on good authority that most of the so-called homeopathists make use of some of the same drugs as we do in the same doses. They, however, do not use drugs to the same extent. This seems to me one of the reasons why they sometimes are preferred to the so-called regular physicians. We frequently underestimate the understanding of the intelligent public. It is a well-known fact that physicians in countries with well-advanced medical education, which is recognized by the public, enjoy a greater confidence than in others, and we do not find so many pathies there. A thorough training of all physicians will have the effect that the different pathies will soon lose their importance. This thorough training in physiology and pathology can, in my opinion, be reached only when the teachers can devote their entire time and energy to those subjects; therefore, they should be well paid in order to be independent of practice.

We see the question of good medical schools is, to some extent, a money question. The states and territories should do properly what most of the private concerns do improperly. If there exist laws preventing this, they should be changed. I may repeat what I said on another occasion: If a law exists which apparently is against the welfare of the community, it must be abolished. A corporation should not be allowed to hide itself behind the screens of antiquated laws.

We now have boards, state and territorial, with executive power; that means, the state and territorial boards control the products of the medical schools. But, is this sufficient? Does a short theoretical examination give a good guarantee that a candidate is thoroughly trained in a profession which is eminently practical? We certainly must answer in the negative. The next step necessary will be the control and ownership of the schools themselves by the various states or territories. If all schools were state or territorial properties they, necessarily, would soon be of equal standing. We would have equally well trained physicians, and there would be no reason for barriers between the states. Here I would call your attention to a clause in the medical laws, reading about like this: "And this Act shall not apply to any commissioned medical officer of the United States Army, Navy, or Marine Hospital Service in the discharge of his professional duties." Why cannot this clause read: "And this act shall not apply to any graduate of a college the efficiency of which is recognized by all boards of the United States?"

The good, even the excellent, work of many of the private schools is not disputed; however, it seems that these cannot excuse the system which makes it possible that so many less commendable schools can flourish. A system which allows only a single poor medical school to exist is a bad system, and it should not be tolerated. Permit me to mention in this connection the report by a committee appointed by the Superintendent of Public Instruction in Michigan, which reads, in part: " . . . have made a report in which they say they were strongly impressed with doubts as to the wisdom of chartering private medical colleges, and state it to be their judgment that if such a policy is to be pursued, the following should be required:

1. A standard of preliminary education should be provided, and a board created to examine all students before entering upon the study of medicine.

2. Some safe, uniform standard for graduation ought also to be fixed and insisted upon, as a condition precedent to a license to practise medicine.

3. The financial solvency and stability of each such institution should be more carefully guarded and insisted upon.

4. Medical colleges should not be chartered in small towns, where clinical and hospital facilities, so necessary to the proper education of a physician, are not ordinarily found.

5. A constant and thorough visitation and inspection of such institutions should be regularly made by a board of visitors competent to judge fairly of their merits.

6. The capital of every medical college should be large enough to warrant the employment of men learned in their profession, and the provision of equipment in all branches adequate to promise a proper medical course.

The committee also says that the capital stock of many of the institutions appears altogether too small to give fair promise of success. . . ."

In a similar way, the *Journal of the American Medical Association*, of May 19th, says, in part: "If there is one thing in which the American medical education leads the world, it is in its quantity, but we do not congratulate ourselves on this fact. What we need is improvement in

quality, and it would be no loss if three-quarters of the hundred and fifty, more or less, medical colleges of all sorts in this country should go out of business. Our medical colleges have been too long originated and conducted as business investments, not always for their direct returns, but to supply from their output a consulting clientele for their professors. The stock company medical college, described by a prominent neurologist in the '70s, was a caricature with a broad family likeness to many of the institutions of the time, and there are still, in some quarters, relics of the same features amongst the medical colleges of to-day."

In this place I must criticise most strongly another state of affairs in our peninsula, in Michigan, because the same conditions might be prevented in another division, and also because it bears directly on the subject under consideration, *i. e.*, the interstate reciprocity for license to practise medicine. We have in Michigan six medical schools, three of them of recent date. Among them there are three in Detroit and one in Ann Arbor. Ann Arbor is about one hour's ride from Detroit. The medical schools in Detroit are private institutions; our state medical school is in Ann Arbor. I warn all friends of medical progress and of good citizenship to follow the example set by Michigan. The state medical institution, or, at least the clinical department, should, by right, be located in a place where the students and citizens of the state derive the greatest benefit from the same, *i. e.*, in the metropolis of the state. If the clinical department of the state medical school would be located in Detroit we could expect that the private medical schools would sooner be closed. This would be in the interest of the people. Ordinary common sense demands the change. I am fully convinced that I express the sentiments of a great part of the profession in Michigan. Rhode Island does not recognize the diploma of the Medical School of Michigan, because Rhode Island does not recognize the diploma of any medical school located in a place which has less than 50,000 inhabitants. Considering all circumstances we may well ask: Is it possible to remove the numerous Chinese walls in our country, or must we admit that the licentiates who are not sufficiently qualified in one part of the country become qualified by simply removing to another part of the Union, or must we admit that the value of human life varies according to the political division? It is not necessary to indulge at length on the absurdity of such a condition.

Nevertheless, even under present circumstances the multiplication of standards is not warranted. The most desirable regulation of the license to practise medicine, we admit, would come from a national board controlling the whole of the United States. This is impossible at present on account of our Constitution. The events, however, of recent times, show that there is another remedy, and this is within our reach.

The fifty-two or more groups could immediately form combinations by bringing into effect the interstate reciprocity for the license to practise medicine. The efforts aiming at this are not of recent date. The progress, however, toward a more general adoption of the principle is very slow, for several reasons. In the first place, much preparatory work must be achieved in the single states, *viz.*, the establishing of adequate medical laws. The character of the laws does not permit, in most cases, the introduction of reciprocity. In the second place, the desire for reciprocity is not understood quite sufficiently by the profession and, especially, by the public; and, third, it has to be brought to the mind of the profession that uniformity of requirements for license to practice medicine will, necessarily, bring about a raising of the standard of requirements in almost every political division, and not a lowering of the same as has been feared by some.

Gradually the idea became familiar that the raising of the various standards might not be a less commendable part of the movement than the convenience and justice toward the profession, and, at last, it appeared that the aim toward a higher medical education is even the more important part of the whole movement. In Michigan, after the medical law had been established, it was the wish of the Wayne County Medical Society (*Physician and Surgeon*, January, 1899) to do their part toward an improvement of conditions. A committee of five was appointed for this purpose. There seemed to be great difficulty in getting the profession at large interested in the movement. After careful consideration it appeared to me that we should begin with the approval of the authorities who are entrusted with carrying out the rules governing the practice of medicine in the different political divisions. We addressed the authorities and asked them various questions, the most important of which were:

5. Would you be inclined to consider favorably the plan of entering into a state of reciprocity with other states or territories which have practically the same requirements for the license of practising medicine as your state or territory has?

6. Would you join in the efforts in working out a memorandum to be presented to the legislative bodies of the different states with the view to introducing a bill as to the subject matter, and would your secretary cooperate with us?

7. Have you any suggestions to make?

We received some kind of an answer from practically all of the states and territories.

The present situation presents itself as follows: (1) Of 52 states and territories, an examination is required in 32 (33, Texas?) and in that part of the Indian Territory which is occupied by the Cherokee Nation. (2) Favorable preliminary answers to our proposition from 38, part of Florida and part of the Indian Territory; 5 undecided, 2 unfavorable. (3) Of the combined answers, given at different times, and

partly expressing the sentiment of the political division; 40 states and territories and 2 parts of 2 other divisions answered favorably; 7 were undecided and 2 may be conditionally classed as unfavorable. (4) The laws allow reciprocity in 12 political divisions, District of Columbia, Illinois, Indiana, Maryland, Michigan, New Hampshire, New Jersey, New York, Ohio, Pennsylvania, Virginia, Wisconsin. (5) Actual reciprocity exists in 2 states, New Jersey and Pennsylvania.*

I may say here that my compilation may admit of improvement. I hope that the members present will correct the same as much as possible.

If I undertake to quote some of the answers received, I naturally do this without blaming any party for the stand taken. Every opinion is honored; it is an old saying that "Out of the differences of opinion the truth is born."

All the answers have been received within a year. I have selected out of their number the following answers, or parts of answers, respecting the law.

1. *Alabama.*

Answer to Question 5. Am not prepared to commit myself on this point now. (No signature.)

2. *Alaska.*

I would say that Alaska has no laws in reference to medical practitioners, except the laws of Oregon, if the District Judge here decides that they are applicable. By the license system attached to a penal code which was passed at the last session of Congress, itinerant physicians in Alaska are taxed fifty dollars per annum. I would be in favor of making the laws as stringent as possible, so as to make it very difficult for quacks and charlatans to practise.

(Signed) John G. Brady,
Governor of Alaska.

3. *Arizona.*

So far as interstate reciprocity is concerned, we have in this territory as yet done nothing, except that we have a tacit understanding in the profession that as soon as such a step is taken in any of the states or territories we will be with them.

It has been the aim of the medical examining board of this territory to so conduct its examinations that they could take a standing with any state in the Union, and it is our intention at the present time to present to our next legislature a bill authorizing the examining board of this territory to recognize the certificates from the examining boards of other states or territories of the Union wherein a like examination is held to that which we require here.

(Signed) Wm. Wylie.

4. *Arkansas.*

Answer to Question 5. No, decidedly not, while the Chicago mills are at work.

Answer to Question 7. Boycott all of the Chicago colleges until they put a stop to their diploma mills. This is their duty to the profession throughout the country.

(Signed) H. C. Dunavant.

5. *California.*

Answer as to reciprocity favorable.

There is no work being done at the present time with the medical law, as our legislature does not convene until next winter, when an effort will be made to secure something more in accord with the present requirements.

(Signed) Chas. C. Wadsworth.

6. *Colorado.*

As our law requires no examination, reciprocity is unnecessary. However, we intend presenting a bill at the next meeting of the legislature on the lines of the Pennsylvania bill, in which, you will remember, there is a reciprocity clause. (Signed) C. K. Fleming.

7. *Connecticut.*

(See Maine.)

8. *Delaware.*

Answer to Question 5. I cannot answer this without the advice of the board.

Answer to Question 6. I think it very probable we would.

(Signed) Irving S. Vallandigham.

9. *District of Columbia.*

The Board of Medical Supervisors of the District of Columbia will issue a license to practise medicine here, without fee and without examination, to any duly licensed physician who may change his residence to the District of Columbia from any state or territory where medical laws and medical examining boards exist, if the medical laws and medical examining boards of such state or territory grant equal rights and recognition to licentiates of said Board of Medical Supervisors of the District of Columbia. The difficulties which exist in current laws in the way of the establishment of reciprocity by this Board can be ascertained by you upon examination of such laws. The requirements of this Board are sufficiently rigid to warrant the recognition anywhere of such licenses as it has issued after examination, as you will see from the accompanying summary of the regulations governing examinations. The chief difficulty in the way of reciprocity seems to be, however, as stated before, in the matter of preliminary education.

(Signed) Wm. C. Woodward.

10. *1st District of Florida.*

Answer to Question 5. Yes. I answer this as to my professional feelings.

Answer to Question 6. Yes.

* Porto Rico: Applicants who hold diplomas from respectable colleges or who have been licensed by any state board in the United States which requires an examination, are licensed without examination. (*Physician and Surgeon*, May, 1900.)

Answer to Question 7. The only suggestion that I can think of that would benefit us now is that, instead of having an examining board for each district, it would be better for all concerned to have only a state board, consisting of a representative from each judicial district, and let the candidate present himself to any member for examination and this member will notify the secretary of the board and he will then send questions (which have been previously arranged by each member in the branches on which they examine) to this member who is to do the examining; after the candidate has completed his examination then the questions on each branch shall be enclosed directly to the members who examine on the respective branches, to be passed on by them and the secretary notified of the result; if favorable, the secretary can then issue the certificate and have the president sign it and send it to the member or candidate.

(Signed) C. B. McKinnon.

11. *Georgia.*

Answer to Question 5. Personally, yes; and I presume the board would be so inclined.

Answer to Question 6. I presume so.

(Signed) E. R. Anthony.

12. *Hawaii.*

Our laws on this subject require examination of medical practitioners applying for license to practise medicine in this territory.

(Signed) Charles Wilcox.

13. *Idaho.*

We favor reciprocity and will help.

(Signed) R. L. Nourse.

14. *Illinois.*

Resolution adopted by the Illinois State Board of Health October 10, 1899.

Resolved, That applicants for a state certificate to practise medicine and surgery in the State of Illinois, who have been examined and licensed by other State Examining Boards maintaining standards not lower than those provided for in the Act to Regulate the Practice of Medicine in the State of Illinois, in force July 1, 1899, shall be granted certificates without further examination on payment of fees required by the Act, providing, that the applicant, who must be a graduate of a medical college in good standing with this Board, shall present with his license an affidavit from the President or Secretary of the State Examining Board showing that the requirements of the said examining board at the time of his examination were equal to those exacted by this Board under the present law, and providing further that the State Examining Board will grant licenses without examination to applicants holding certificates issued by the Illinois State Board of Health under the Act now in force.

Note: Under the provisions of the Act to Regulate the Practice of Medicine in the State of Illinois, in force July 1, 1899, an applicants for a certificate to practice medicine and surgery in the state must present evidence of being a graduate of a medical college in good standing, as may be determined by the Board, and must pass an examination in those general subjects and topics a knowledge of which is commonly and generally required of candidates for the degree of doctor of medicine by reputable medical colleges in the United States. No medical college will be considered in good standing after January 1, 1900, which does not require of all graduates receiving diplomas after that date, as a condition of graduation, an attendance upon four full courses of lectures in four separate years.

15. *Indiana.*

So far we have been unable to establish reciprocal relations with any State Boards.

(Signed) Wm. T. Curryer.

16. *Indian Territory.*

(Creek Nation.)

Answer as to reciprocity favorable.

In reference to medical practice in the Indian Territory, will say in reply that in the Cherokee and Creek Nations a regular diploma can be registered, for which a fee of five dollars is charged; otherwise a charge of twenty-five dollars is made for examination.

The Seminoles employ a reputable physician on a salary of $1,250 per year, with the privilege of doing outside practice.

The Choctaws and Chickasaws require examination in all cases—for which twenty-five dollars is charged—which, in my opinion, should obtain anywhere.

(Signed) Geo. W. West.

17. *Iowa.*

Answer to reciprocity favorable.

The statute itself, and not any rule of the Board, declares that applicants for certificates must be examined by the Board. There is no way to avoid this unless the law itself is changed. Our legislature has adjourned and will not assemble until 1902.

(Signed) J. F. Kennedy.

[To be continued.]

MEDICAL PROGRESS.

Absence of Vagina.—Carl Beck (*Annals of Surgery,* October, 1900) created a vagina which one year after operation was functionally useful. His patient had no vagina, no uterus and no appendages. The method pursued was a follows: Above the symphysis a transverse incision was made exactly as if a cystotomy were being done. A catheter was passed into the urethra and retained as a guide. Blunt dissection with two thumb forceps was done until the vulva was reached, when upon a long director the extravesical cellular tissue was divided near the ure-

thra. Two flaps were taken from the inner aspects of the thighs with their bases at the vulva. After liberal dissection of these, with their skin surfaces apposed to each other and their raw aspects corresponding with the canal already made as above, they were drawn upward until their apices could be secured above at the suprapubic wound. The usual tamponade made a good canal which aside from a little contraction was serviceable. The wounds along the thighs were closed on general principles.

Total Gastrectomy.—V. De Carvalho (*Lancet*, September 15, 1900) records the case of a Brazilian mulatto woman, aged forty-six years, whose emaciation had advanced so continuously that she weighed but sixty-eight pounds; she had always suffered more or less from gastric pains since her youth, with recurring attacks of gastralgia followed by vomiting (occasionally of blood), becoming more frequent and severe. On examination a tumor, the size of a turkey's egg, was found in the right epigastric region close to the costal margin, the tumor being movable and painless on deep pressure; a median excision extending from the ziphoid cartilage of the sternum to the umbilicus was made and the tumor exposed; owing to the adhesions of the stomach to adjacent viscera, gastroenterostomy which had been contemplated was deemed inadvisable; hence, gastrectomy was decided upon and performed in the usual way, great difficulty being experienced in enucleating the stomach and in approximating the duodenum to the esophagus. Although the patient's condition was poor during the operation, requiring stimulation, and the introduction of artificial serum intravenously, the patient came out from operation nicely; rectal feeding was continued for six or seven days; at the end of the ninth day the superficial wound had healed and the patient was able to take small portions of solid food, which were readily digested. This is the fourth successful operation thus far recorded, being the first one to be done successfully in Brazil.

A New Spinal Brace.—In Pott's disease of the spine in which a skin slough had formed over the hump, E. A. Tracy (*Pediatrics*, September 15, 1900) used a half-inch board splint extending from sacrum to neck, and having a hole 2½ x 3 inches to receive the hump. The splint was padded with cotton and felt pads were attached to lie on the lateral processes of the diseased vertebræ. This exerted pressure for correction of the deformity, while it permitted the slough to be dressed. When the skin had healed two pieces of wood plastic material were attached to the board and moulded upon the child's body, one so as to embrace the chest, the other the pelvic bones. The brace cannot be put on wrong, may be removed once a week and snugly reapplied, and the pressure-pads can be changed or reinforced at will. a tightly-fitting undershirt is worn beneath the splint.

"Reminiscences" and Minor Epilepsy.—Careful study of the slighter forms of epilepsy frequently tend to throw some light upon the way the normal mental processes are carried out. The immediate effects of an epileptic fit depend upon the intensity of the localization of the nervous discharge. H. C. Thomson (*Practitioner*, September, 1900) says that there are three conditions which may arise from the discharge: (1) There is an overactivity of the part in which the discharge occurs, and subjective sensations corresponding to the function of that part are revealed. (2) The overactivity is accompanied or immediately followed by a negative condition which may be the predominant feature of the attack, and is manifested by a momentary loss of consciousness. (3) When the higher centers are involved, their control over the lower centers may be lost and the lower centers may cause acts of which the higher centers never become conscious. This is illustrated by the many automatic acts performed. One of the most interesting memory defects often associated with epilepsy but also occurring in healthy people is the so-called "reminiscence." This is a strange evanescent feeling of familiarity with some place or event which occasionally crosses the mind although the place is being visited or the event happening for the first time. One explanation of this rather common phenomenon is based on the idea of a previous existence. Another supposes that the two hemispheres do not act synchronously. Some have supposed them to be connected with dreams of somewhat similar plans or events. The author believes them to be due to temporary negative conditions of consciousness, probably due to some slight nervous discharge. He supposes that the first impressions of the room, for instance, do not rise into consciousness due to the temporary negative condition, but a moment later the scene is revealed together with this faint recollection of a distant event. Their occurrence must be considered abnormal and due to a localized discharge of nervous energy. A sudden increase in the frequency or intensity of sensations should be viewed with suspicion and should lead to a careful inquiry for other symptoms of a developing epileptic state.

Thrombosis in Pelvis and Lower Extremities.—K. Lennander (*Lancet*, September 15, 1900) reports that since resorting to elevating the foot of the bed of patients immediately after operation that the occurrence of post-operative thrombosis has decreased materially, probably owing to the mechanical aid afforded by this position in returning the venous blood from the extremities. Usually the foot of the bed should be elevated from six to twelve inches. In cardiac lesions, it is advisable to elevate the foot of the bed from ten to nineteen inches, gradually lowering this elevation some days after operation. Cardiac tonics such as digitalis, strychnine, etc., should also be employed in these cases; it is also helpful to massage the legs of some patients after

operation as this favors return circulation, provided the patient has not already had a thrombus; in laparotomy cases this method of elevating the foot of the bed is also beneficial.

Fractured Patella.—W. B. Trimble (*Med. Rec.*, September 29, 1900) advocates the following treatment as being most likely to give permanent good results. The knee is put in a soap poultice twenty-four hours prior to operation; on the morning of the operation it is thoroughly scrubbed with water and green soap, then washed with a solution of bichloride of mercury, 1-2000; this is followed successively by turpentine, alcohol, ether and lastly bichloride again; the incision is made transversely between the fragments, opening the joint; all blood-clot is washed away by continuous irrigation (bichloride of mercury, 1-2000) and the ragged aponeurotic fringe is lifted from between the broken pieces. Each fragment in turn is drilled, beginning one-eighth to one-fourth of an inch behind its fractured edge, going directly through; silver wire is used, about the size of or possibly a little larger than the lead in an ordinary lead pencil, it being filed sharp on each end to facilitate insertion; the pieces are drawn together by main force, and the wire is twisted tightly, holding them in apposition; the ends are then cut, the wire being hammered down flat on the bone; the subcutaneous tissues are then sewed down over the bone with heavy catgut; a drainage-tube is inserted in the wound, coming out of the most dependent part of the outside of the joint, a small incision having been made on the end of a Tait forceps pushed down through the original wound; a small bunch of horsehair drains is then laid across the patella in the same line as the original incision, each end protruding about one inch; the skin is then stitched with silk; the wound is dressed on the third day and the horsehair drain removed and possibly the drainage-tube; however, the tube may be left in until the second dressing if desirable. After ten days the wound should be entirely healed, and at the end of the second week passive motion should be begun, the patella being daily pushed from side to side, each day more forcibly than the preceding; at the end of the third week, flexion should be started and continued daily by the surgeon, until six weeks have elapsed since the time of the operation; the patient then should be allowed to use his limb, keeping up active motion, but carefully, until ten weeks have elapsed since the time of the operation.

The Ileocecal Orifice in Constipation.—W. J. Mayo (*Annals of Surgery*, September, 1900) narrates the case of a woman, aged twenty-one, who gave a history of chronic constipation with attacks of right-sided abdominal tenderness, lasting for several days at a time. These attacks recurred so often that an operation for appendicitis was advised and done; the appendix was found practically normal, except for a few adhesions; it was noticed at the operation that the small bowel was quite full of material in spite of the previous energetic purgation. At the junction of the ileum and cecum the caliber of the gut was markedly reduced, having the appearance of being constricted as if tied with a string; convalescence was uneventful, but the constipation and pain persisted until four months later, when she was again operated on, the ileocecal coil being exposed. An incision, two and one half inches in length, was made at right angles to the ileocecal orifice, having its center at that point; the wound was sutured transversely after the manner of the Heineke-Mikulicz pyloroplasty, making a very considerable increase in the size of the aperture between the ileum and cecum; recovery followed with a disappearance of both the constipation and localized pain. This case is interesting as throwing some light on the function of the ileocecal valve, which consists of two semilunar folds of mucous membrane situated one superiorly and the other inferiorly, leaving a transverse slit between at the point of junction of the ileum and cecum; immediately at the base of the valves is a circular fold of muscle fibers, forming a constrictor muscle having much the appearance of the pylorus; the main function of this valve seems to be to prevent the too rapid emptying of the small bowel and to maintain some pressure against peristalsis until the process of small-bowel digestion is properly completed; hence, if the barrier to ready egress be excessive, partial retention of small-bowel contents results with small-bowel constipation and its resulting train of symptoms, due to fermentation and absorption.

Adhesions About the Stomach.—A. T. Cabot (*Annals of Surgery*, July, 1900) describes adhesions about the stomach and duodenum not associated with malignant disease or any still active inflammation of that region; these adhesions arise as a result of a variety of inflammatory conditions, *e. g.*, inflammation of the gall-bladder; ulcers of the stomach and duodenum and of the transverse colon extending to the peritoneal coat of the infected viscus, causing it to adhere to the surrounding parts; and inflammations in and about the pancreas, usually so severe as to be fatal. The adhesions may be thin and lax or tough, firm, and thick, their effect depending more upon their situation than upon their density; dense adhesions may give no symptoms if they do not lead to distortion of the organs; while light adhesions between the stomach-wall and the duodenum may produce a decided kink of the pylorus and so interfere with the permeability of this orifice; constricting bands may cause dilatation behind the point of obstruction; the organs usually bound together are the pyloric end of the stomach, the first part of the duodenum, the transverse colon, and the gall-bladder, with adjacent portions of the liver. The previous history of the patient often points to some earlier attack or attacks of biliary colic or of gastric or duodenal ulcer, which may have

occurred many years before and have been followed by a long period of comfort; usually, however, digestive disturbances and pain are the prominent symptoms; the former usually appear as attacks of violent indigestion either continued or with intervals of comfort; the pain is usually a marked feature; it may be moderate in degree or excessive, in which case it is spasmodic and lancinating, not unlike that of biliary colic. When the severe pain occurs as a distinct attack, it usually lasts but a relatively short time, rarely more than a few days, and usually is of a distinctly intermittent character; the pain is usually referred to the epigastrium and the right hypochondrium; in one case the pain which began in the epigastrium extended along the costal border of the right side until it encircled the body, vomiting and inability to take food being present during this time. The diagnosis of adhesions is not easy, but a long-enduring liability to attacks of gastralgia, for which a careful study of the gastric functions fails to suggest an adequate explanation should lead one to expect adhesions; also attacks simulating biliary colic without jaundice justify a like suspicion; in either case an exploratory operation is not only justifiable but is called for, the operation being easily done and not fraught with danger.

New Test for Typhoid in Feces.—That the Eberth bacillus is always present in the stools of those affected with typhoid fever and absent in other conditions is a proposition the truth of which can be demonstrated, in the opinion of L. Rémy (*Public Health Reports,* September 21, 1900), by the employment of a proper culture medium. The contradictory and inconclusive results obtained by previous investigators he ascribes to the unsatisfactory character of the gelatin used, even the potato gelatin of Elsner, the most successful medium, being unreliable on account of its variable chemical composition. To overcome these objections, the author prepared a differential gelatin, closely resembling the potato in chemical composition. The constituents are as follows: Distilled water, 1000 grams; asparagine, 6 grams; oxalic acid, 0.5 gram; lactic acid, 0.15 gram; citric acid, 0.15 gram; disodic phosphate, 5 grams; magnesium sulphate, 2.5 grams; potassium sulphate, 1.25 grams; sodium chloride, 2. With the exception of the magnesium sulphate, the above salts are powdered, mixed with the water and 30 grams of Witte's or Grubler's peptone and heated under pressure for a quarter hour. The solution is then added to 120 to 150 grams of gelatin, shaken and made slightly alkaline with soda solution. After a second heating similar to the first, one-half normal solution of H_2SO_4 is added until 10 cc. of the solution are neutralized by 0.2 cc. of one-half normal soda solution. The solution is then shaken, placed in a steam sterilizer for ten minutes and filtered, after which the acidity is verified. The magnesium sulphate is now added and the solution is placed in tubes containing 10 cc. each and is sterilized three times. Just before using, 1 cc. of a 35-per-cent. solution of lactose and 0.1 cc. of a 2.5-per-cent. solution of carbolic acid are added to each tube. By means of this differential gelatin, 31 observations were made of the stools of 23 typhoid-fever patients. In three instances only were the results negative, and in each of these three cases other observations were positive. In no case, therefore, was there failure to find the Eberth bacillus. On the other hand, it was absent from the stools in every one of 12 cases of various other diseases. As a result of his investigations the author believes himself justified in claiming that his differential gelatin is a practical and certain medium for the isolation of the typhoid bacillus in the presence of the colon bacillus, by the plate method. Further, that the Eberth bacillus is the pathogenic element in typhoid fever and that its presence in the stools is the only sign which is competent of itself to establish the diagnosis of the disease.

Antiplague Serum.—H. D. Geddings (*Public Health Reports*) believes that both the Haffkine prophylactic and the Yersin antiplague serum have demonstrated their great superiority to all other known measures for the prevention and cure of bubonic plague. For the latter purpose, the Yersin serum only is available, as the prophylactic, being itself a product of the plague bacilli, is distinctly detrimental to a person already infected with the disease. As preventives both remedies are effective, but the differences between them are so marked and numerous that there is seldom any question in given circumstances as to which should be preferably employed. Where actual infection is probable, as in the cases of those in the immediate vicinity of a plague patient, the Yersin preparation is indicated, as its action is prompt and directly antagonistic to the malady. On the other hand, its immunizing effect is so temporary, about two weeks, and its production is so expensive that it is not eligible for the protection of those not already exposed, especially if in large numbers, as when an entire community is threatened by an advancing epidemic. In such circumstances recourse should be had to the Haffkine prophylactic which can be produced rapidly in large quantities and at small cost. Its inoculation is followed in a few hours by a local and constitutional reaction which, though generally mild, may be fairly severe, in which respect it contrasts unfavorably with the Yersin serum. The latter possesses the additional advantage, when properly prepared, of keeping almost indefinitely, whereas the former deteriorates under the influence of air and light and cannot be depended on for a longer period than six months. Although the immunity conferred by the Haffkine prophylactic usually persists for several months, it is not absolute, as is demonstrated by the not infrequent development of the plague in vaccinated persons, but the death-rate is low in such circumstances. Experience has shown the advi-

sability of a second inoculation about ten days after the first. The Yersin serum is a true antitoxin, produced by subjecting a horse to successively stronger injections of plague toxin, the process requiring the greater part of a year. Occasionally its completion necessitates the inoculation of the animal with a live culture of the bacillus. The Haffkine prophylactic, on the contrary, is a toxin prepared by growing cultures of the bacillus for a month and then destroying the organisms by subjecting them to a temperature of 70° C. for two hours. As illustrative of the utility of both first and second vaccinations with the prophylactic, the author quotes the following statistics of observations made in Shanvar, India: *Inoculated once,* 5712, attacks, 69, deaths, 31; *inoculated twice,* 3349, attacks, 9, deaths, 5; *not inoculated,* 5614, attacks, 957, deaths, 756.

Malignant Diphtheria.—That an attenuated diphtheria germ may, in new soil, cause the most virulent form of the disease is well shown by Dr. Coriveaud (*Journal de Médecine,* September 9, 1900). In an epidemic of mild cases one child had recovered and was dismissed from the hospital as cured, but had still a slight discharge from a suppurating submaxillary gland. A few days later, in a neighboring town, it slept with another child, and nine days afterward this latter developed an extreme diphtheria poisoning and died. Six days later a brother was attacked, followed in eight and eleven days by two other children. All exhibited marked asphyxia, not due to the membrane but to the excessive toxemia; all were given antitoxin, but each succumbed within two days of the attack.

Xanthoma Diabeticorum.—A case of this relatively infrequent disease of the skin is reported by Samuel Sherwell and James C. Johnston (*Jour. Cutaneous and Genito-Urinary Dis.,* September, 1900). The patient was an American woman, forty years of age, and somewhat plethoric and stocky in build. She had always been in fairly good health; was married and had had four children and four or five miscarriages. These apparently had no effect upon the skin lesions. The first lesions were noticed about five or six years previously, first on the arms, elbows, the knees and the nates. They have been relatively less marked during the summer months, but have been fairly constant. They have gradually increased in extent and intensity each year. During the last year the symptoms have become so very distressing that she could get no relief night or day. There was great pain on using her hands, on standing or walking, and on sitting or lying down. Sleep was almost impossible. The tubercular masses in the skin felt and caused a sensation as if peas or shot were in her skin when she laid herself down. If one looked at the patient standing nude a little distance from the observer, the eruption might have been taken for a case of variola at the height of the pustular and confluent stage of that disease. There were narrow, dark-red inflammatory halos around all the tuberculate and conglomerate masses, some of which rose as much as a quarter of an inch above the level of the skin. The tops of the elevations were rather conical in shape, of a bright yellow (xanthomatous) character, and were hard and resistant to the touch. These lesions were most numerous on the extensor surfaces of the arms and legs, and on the back and nates. No part of the body was free from the lesions, except the eyelids. On examination of the patient's urine it was found to be normal in reaction, sp. gr., 1021, slightly albuminous, and to contain an enormous quantity of sugar. From the history of the amount of water she passed, her thirst, etc., it is probable that the glycosuria had existed since the skin lesions appeared. On antidiabetic diet and mild laxative alkaline treatment she improved considerably. The glycosuria has not disappeared, but is now comparatively slight. Sherwell believes that this disease is not a true xanthoma, but an inflammatory condition resembling that affection, occurring in diabetics. Johnston describes at some length the histology of the disease. Two illustrations of the case accompany the paper.

Tuberculous Lymphadenitis and Pseudoleukemia.—The idea that Hodgkin's disease is of infectious origin is by no means a new one. Many bacteria have been isolated from the glands of such cases, but recently careful investigations have proven the tuberculous nature of severe cases agreeing clinically with those of pseudoleukemia, and showing after death lesions pointing to the latter condition. F. R. Crowder (*N. Y. Med. Jour.,* September 15 and 22, 1900) reports in detail a case which appeared clinically to be one of pseudoleukemia and describes fully the lesions which were afterward found in the various organs, proving how difficult it is even with the aid of the microscope to distinguish between a tuberculous and non-tuberculous glandular hyperplasia. The tissue is not at all characteristic of tuberculosis and when the germs are few they may be difficult to demonstrate. The inoculation experiments are frequently necessary. In the author's case the diagnosis of pseudoleukemia had been made, but microscopical examination showed the tuberculous nature of the condition. Two inoculation experiments proved negative in this instance. There was no new or old tuberculous lesion of the lungs, but there were tubercles in the liver, spleen, kidneys and peritoneum, and further investigation showed that the other lymphatic and visceral lesions which pointed plainly to pseudoleukemia were really tuberculous in origin. The literature upon the subject is reviewed and a large number of cases which appeared to be examples of Hodgkin's disease have been found by bacteriological experiments to be due to the tubercle bacilli, although the clinical symptoms and the anatomical lesions were characteristic of pseudoleukemia. It is not fair to say that all

pseudoleukemias are even probably tuberculous in origin, but it has been abundantly proven that tuberculous lymphadenitis may give rise to all the symptoms and anatomical findings of that disease and undoubtedly more complete analyses in the future will demonstrate this specific cause in a large number of so-called pseudoleukemic cases.

Acute Leukemia.—Being among the rarest of blood-diseases, the acute form of leukemia is not as a rule described in the usual text-books. A. Dennig (*Münch. med. Woch.*, Sept. 18, 1900) finds that it may occur at any age, though most often in adult males, and that it comes on suddenly in those previously in the best of health. Extreme malaise and weakness force the patient to go to bed; soon headache, pains in the limbs and often difficulty in deglutition are added. Stabbing pains in the splenic region, palpitation of the heart, vertigo and syncope may develop. Furthermore an increasing pallor of the skin, fever and hemorrhages from the skin, mucous membranes or into the organs, appear early. The gums are often swollen and bleeding and scurvy may be suspected. In the subsequent course of the disease the spleen usually swells, but rarely to the degree of chronic leukemia, and the same may be said of the liver and the lymph-nodes. Bronchitis or bronchopneumonia, hemic murmurs, increased frequency, smallness and irregularities of the pulse and tenderness of the bones are often noted. Of great diagnostic importance is the examination of the blood. There usually is a considerable increase in the mononuclear elements varying from the size of a red cell to twice as large and possessed of a large, round, faintly-staining nucleus surrounded by a narrow zone of protoplasm which is not granular and which possesses no special affinities for neutral or basic dyes. The red cells show the changes of a severe anemia. The appearance of the blood is not, however, absolutely diagnostic since a similar picture may be found in chronic lymphatic leukemia. Too few cases have been observed to prove the asserted micro-organismal character of the disease. The prognosis is unfavorable, since no known remedies stay its progress.

Diagnosis of Gout.—The frequency of gout and the ease with which it may be overlooked is dwelt upon by A. Strumpell (*Münch. med. Woch.*, Sept. 18, 1900). Although many different joints may be involved, these most frequently belong to the lower extremities and are most distally situated from the trunk and the first metatarsophalangeal articulation is rarely spared. Another important diagnostic feature is the usual monarticular character of gout; at all events it is very rare to have more than two or three joints affected at the same time. The short duration and the great frequency of the attacks are peculiar, as is also the appearance of intense swelling which a gouty joint gives. Not very rarely chronic gout is mistaken for arthritis deformans, but the history of previous acute attacks and the presence of tophi and perhaps of a sclerotic kidney will prevent this error. Often errors arise in that advanced gout manifests itself by symptoms not emanating from the joints, as tarsalgia, achillodynia, or more seriously as chronic nephritis or arteriosclerosis. An interesting fact is that two other diseases of nutrition, diabetes and obesity, not rarely occur conjointly with gout, so that the metabolism of all three great classes of foods may be disturbed together. Disturbance of proteid metabolism, causing gout; of carbo-hydrate reduction, diabetes and of fatty obesity. The etiology factors chronic alcoholism and lead intoxication may aid in doubtful cases in making a diagnosis.

Action of Chrysarobin.—From a microscopical study of the skin treated with chrysarobin plaster, M. Hodara (*Monatshft. f. prakt. Dermatolog.*, Sept. 15, 1900) finds that this causes a homogenization and necrosis of the granular and part of the prickle-cells of the epidermis with pigmentation of the lower cornified strata. If used in greater strength there will be edema and severe inflammation of the cutis and intra- and intercellular edema of the prickle-cells of the epidermis with the formation of seropurulent vesicles. Below the necrotic layers a new and more extreme layer of prickle- and granule-cells will develop.

Anilin Blue in Malaria.—Since its introduction by Laveran in 1891, methylen blue has been used with varying success not only in the treatment of malaria, but also in other diseases, such as persistent headache, neuralgia, rheumatism and as a sedative in insanity. Contrary to the earlier view, however, it has been found that in spite of the affinity of the malarial parasite for this substance staining of the hematozoon does not take place in the circulating blood and some other theory must be advanced regarding its action. In order to determine whether this was due to the chemical constitution of the agent, Alexander Iwanoff (*Deutsch. med. Woch.*, Sept. 27, 1900) experimented with another dyestuff, choosing anilin blue which differs from methylen blue in composition and also in belonging to the acid not the basic group of stains. Fifteen carefully selected cases were treated with anilin blue alone, receiving 5 grains three times a day, with the result that in 7 the malady promptly terminated by lysis and the organism disappeared from the blood. No unpleasant by-effects were noted; in particular, the distressing vesical and urethral irritation so often accompanying the use of methylen blue was entirely absent, while the percentage of cures is about the same for the two drugs. The conclusion reached is that the action of methylen blue is independent of its chemical formula, other stains having the same effect, and that in the anilin products there still remains a vast amount of unexploited therapeutic material.

THERAPEUTIC HINTS.

Baldness.—About once in two weeks the scalp should be thoroughly cleansed with tincture of green soap as a shampoo, and the following well rubbed in once a day:

℞ Resorcin ..... 4.0 (℥i)
Ac. salicyl..... 1.0 (gr. xv)
Ol. ricini..... 0.5 (gtt.viij)
Alcohol .....30.0 (℥i)

After two or three weeks this latter may be replaced by

℞ Hydrarg. chlor. corros.. 0.5 (gr. viij)
Betanaphtol ..... 3.0 (gr. xlv)
Ol. ricini..... 1.0 (♏ xv)
Alcohol .....90.0 (℥iij)

Albuminuria of Pregnancy.—James W. McLane orders rest in bed, plenty of fresh air, skimmed-milk diet, with no alcoholic liquors, half a gallon of water (not mineral water) a day to flush out the kidneys, a daily warm bath, and when needed the following pill:

℞ Ext. Colocynth. Comp. 0.1 (gr. ij)
Mass. Hydrarg..... 0.09 (gr. iss)
Ext. Nucis. Vom..... 0.01 (gr. 1/7)
Pulv. Aloes..... 0.03 (gr. ½)

For an acute case he advises venesection, if plethoric, or dry or wet cupping over the loins, with free catharsis by compound jalap powder, or calomel, gr. x, and sod. bicarb., gr. xx. If there is no relaxation of the symptoms, induce labor as soon as the child is viable.

Ichthyol in Trachoma.—M. Eberson (*Therap. Monatsh.*, Vol. XIV., p. 313) gives the clinical histories of five cases of trachoma, illustrating the good results afforded by ichthyol in this otherwise intractable disease. He differentiates two forms of the disease, a dry or mild and a moist or severe. The former is best treated with copper sulphate, but the latter requires more energetic measures. The method followed by the author is first to wash the everted lids with a solution of corrosive sublimate, 1-5000, to remove pus, mucus, etc., and to cause a slight mechanical hyperemia. The friction must not be too severe, otherwise the conjunctiva is made to bleed. A few drops of pure ichthyol are applied with the rounded end of a glass rod and spread out in a rather thick layer. This is allowed to remain a few seconds, or until the patient feels the burning pain no longer, when it is then washed away with clean water by means of cotton. It is sometimes advantageous to employ a fifty-per-cent. ichthyol solution for the first few applications, and then to proceed to undiluted applications. This treatment relieves the severe, annoying symptoms accompanying trachoma, without incurring noteworthy pain, and without giving rise to cicatrices. At the same time, it almost entirely removes all danger of infection.

Urticaria.

℞ Pul. Calaminæ ..... 8.0 (℥ii)
Aq. Calcis .....250.0 (℥viii)
Acidi Carbolici ..... 2.0 (℥ss)
M. Use as a lotion.

If not sufficient to allay irritation, and burning is extreme:

℞ Menthol ..... 0.6 (gr. x)
Adipis .....30.0 (℥i)

Typhoid Fever.—A. Schmidt (*Montreal Med. Jour.*, Aug., 1900) calls attention to the value of the almost forgotten "Woodbridge treatment." Three different formulæ are used, as follows:

No. 1. Res. podoph. 0.00006 (gr. 1/960)
Calomel ....
Guaiacol carb.
Menthol ... aa. 0.004 (gr. 1/16)

No. 2 is the same except that guaiacol is increased to 0.015 (¼ grain), and thymol, 0.004 (1/16) grain), is added.

No. 3. Guaiacol carb..... 0.18 (gr. iij)
Thymol ..... 0.06 (gr. i)
Menthol ..... 0.03 (gr. ss)
Eucalyptol ..... 0.3 (♏ v)

In capsule.

During the first forty-eight hours give No. 1 every fifteen minutes while awake. After twenty-four hours give also No. 2 every fifteen minutes until five or six free evacuations of the bowels are secured. Then No. 1 is discontinued and No. 2 given less frequently, so as to keep the bowels moving once or twice a day until the temperature is normal. On the third or fourth day No. 3 is given, one every three of four hours. About the fifth day No. 2 is discontinued, and teaspoonful doses of saturated solution of chlorate of potassium are administered every three hours. After one or two days this is stopped and No. 2 again exhibited as freely as possible without causing too frequent evacuations of the bowels. Should the slightest symptom of ptyalism supervene, No. 2 must be discontinued and the chlorate of potash resumed. During the entire treatment every dose of medicine must be washed down by water.

Fireman's Colic.—Firemen on board ship are subject, writes Willis Cummings (*Merck's Archives*, Aug., 1900) to a "colic," with acute pain, extreme prostration, bloodshot eye, much thirst, labored breathing, irregular heart, and agonized expression, a condition which does not yield to *Sun* Cholera Mixture or other cramp remedies. As these men drink large quantities of water, he has been able to prevent this colic by adding to each gallon of water

Calcium phosphate
Sodium phosphate
Potassium phosphate..aa. 17.0 (256 grs.)

with a little oatmeal and ice. A man drinks approximately this amount in four hours while "firing." It was noticeable that the men taking this mixture had much less craving than usual for alcoholic drinks.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, OCTOBER 27, 1900.

NEW YORK'S PLAGUE.

If one of our yellow journals should blurt out in ten-inch headlines, "Eight thousand dead of the Plague in New York City, Thirty thousand more likely to die," it is probable that the city would be aroused to the point of panic, and that prayers and dollars would be poured out wildly to check the spread of the disease. And yet because a plague which during 1900 carries off 8000 of New York's citizens is consumption, a respectable family disease, instead of the loathsome rat and flea bubonic plague, it will take oratory, wire-pulling, persuasion, threatenings and sentimentality to present to the many-minded public any conception of that duty which their own common sense should point out to them, *viz.*, the provision of municipal treatment for the disease, to cure incipient cases and to check the spread of infection.

For forty-five years, ever since Peter Cooper headed the first movement in this direction, there has been a desire on the part of enlightened citizens and physicians to bring about such a reform, but for lack of municipal encouragement it has found expression only in private charities. In the meantime between one and two hundred thousand of the inhabitants have been cut off before their time by this, the city's scourge.

It is an easy thing to bandy words on the subject of reform. The optimist would have tuberculosis become an extinct disease, and all its saved victims centenarians; the pessimist sees in it one of the natural means of wiping out the surplus, for the benefit of the survivors. The man of common sense, and especially the physician, knows that it is a death more cruel to the laboring poor than the sudden terrorizing plague, and a death that though inevitable to some can be prevented for most with proper treatment. He sees in it a cause of desperate poverty, and of wide contagion, for the streets, the air, the public conveyances are full of it; and there is no rattling of bones, or hollow cry, as of the leper, to warn the passer-by to beware.

Perchance there was the same lethargy in the fabled city, when the hundred young men and maidens were led out each year to the Minotaur. Impossible to kill him! All must die! and what an expense to the commonwealth to force a war on the monster! And so the annual 8000 deaths of our city cause us no particular alarm, though every man, woman and child that walks the streets knows vaguely that it may be his turn next.

For a practical straight-forward discussion of the subject we commend to our readers the article by Dr. Alfred Meyer, "The City and Its Consumptive Poor," in this issue, in which he brings the subject down to the level of dollars and cents, and puts the matter in a strong, plain light; so that the physician, the politician, the tax-payer and the philanthropist can all see the subject in its practical aspects. We would also refer them to the discussion held at the New York Academy of Medicine (see p. 671) of this issue.

It is not the policy of New York City to recognize a need and then beg off on the ground of expense or expediency. The discovery of the infectious nature of tuberculosis adds the unanswerable argument to all the philanthropic and economic arguments of the last half century. To dally with the question another fifty years, even for another decade, is to play the part of the improvident householder who buys rare pictures and rugs, and engages expensive teachers for his children, but neglects his plumbing.

Our city parks, and well ventilated schools, our museums and libraries, are all essential to the city's prosperity, but down at the very basis of our municipal being is the need to observe the laws of health.

THE PROBLEMS OF GASTRIC ULCER.

The closer analysis of conditions affecting the gastrointestinal canal is yearly becoming more prominent. In this age in which the frying-pan is characterized as the great enemy of civilization, the general practitioner welcomes any addition that can increase his diagnostic acumen or his facilities for treatment of dyspeptic ills. For this reason a recent paper by Dr. Joseph Frank Payne (*British Medical Journal*, September 29, 1900) is of interest.

From a study of the statistics of St. Thomas' Hospital, London, he is led to believe that there is an actual increase in the number of patients suffering from gastric ulcer. From 1870 to 1895 the numbers have gone from 30 to 216. That this increase is not the result of better diagnostic methods is evidenced by the fact that the fatal cases have increased in about the same proportion and certainly these have been recognized postmortem. He therefore propounds the question, Is the disease more common than formerly and does it affect people of a social grade higher than the typical servant class in which it is so commonly described?

The question of diagnosis has not varied much for many years. The cardinal symptoms are still pain in the stomach at certain times, referred to definite locations; gastric irritability with vomiting of food and hemorrhage, evidenced in the vomit or stools. One new diagnostic feature alone has been added within the past thirty-five years, that of hyperacidity of the gastric fluid, due to excess of hydrochloric acid. The impression gained is that hematemesis associated with other gastric symptoms is one of the most trustworthy of all the signs. It is not positively diagnostic however.

The prognosis is good but a striking contrast in this respect is to be noted between men and women. In males 22 per cent. of his patients died, while among the females but 6 per cent. succumbed. Recurrences are quite prone to happen.

On the important subject of treatment Dr. Payne has a number of suggestions. Rest is an essential. The withholding of all food from the stomach is imperative and rectal feeding is clearly indicated. Notwithstanding theoretical objections relative to the non-absorbability of the colon mucous membrane, the use of peptonized food is of value. Plain milk or unmodified egg preparations are not used by Dr. Payne. The usual denial of water to quench thirst with the substitution of small lumps of ice is held to be unnecessary. Water may be given in moderation. It is moreover a distinct adjunct to the intestinal feeding in the maintenance of the patient. One week of rectal alimentation without water is badly borne, but with water patients bear up well for weeks or even longer periods. The main danger in rectal feeding is not emaciation but heart collapse, and during the second week of such feeding great care is to be observed.

The occurrence of acetonuria accompanying colon alimentation is interesting and suggests the query of its origin. Is it a product of the gastric ulcer or is it due to the type of feeding, or the extreme restriction of the diet? Of drugs, the bismuth preparations and nitrate of silver have promised most. Their action is entirely local, and their suitability appears to depend on the fact that they are not absorbed, or very slowly, and therefore do not produce vomiting or general toxic effect. The question of the treatment of perforation is purely surgical.

THE BACTERIOLOGY AND THE SERUM-TREATMENT OF WHOOPING-COUGH.

The marked infectiousness of whooping-cough determines that disease so clearly to be of bacterial origin that it must be considered a little disappointing that the actual causative factor has not yet been isolated and the way for the production of a protective and curative antitoxin opened.

Even before the science of bacteriology had attained its present development, efforts were made to discover the existing agent of pertussis, but the first important contribution in this connection was made in 1887 by Afanassiew, who described a minute rod in the expectorated matters from children suffering from the disease, and which, when injected into the trachea of young dogs, excited paroxysms of whooping-cough. These observations were subsequently confirmed by a number of investigations. Meanwhile, however, Ritter, in 1892, described a diplococcus as the etiologic agent; and, then, Czaplewski and Hensel, in 1897, isolated a small bipolar rod resembling the influenza-bacillus; although inoculation-experiments were not in either case successful. These latter observations also have been confirmed, among others by Joseph Walsh and G. Arnheim (*Contributions from the William Pepper Laboratory of Clinical Medicine*, Philadelphia, 1900, p. 450; *Berliner klinische Wochen-*

schrift, 1900, No. 32, p. 702), the former, in a series of twelve cases with one autopsy, finding the Czaplewski-Hensel bacillus in the expectorated matter in eight of the nine cases examined and in the tissues after death, and the latter obtaining similar results in forty-four cases, including three autopsies. Examination of the sputum from a child at the height of an attack of whooping-cough, spread upon a cover-slip and exposed to the action of dilute carbol-fuchsin, will reveal with powers of sufficient magnification a large number of small bacilli, sometimes arranged in short chains, stained at the extremities, generally without, but sometimes within, the cells. The organisms can be stained also by the methods of Gram, Weigert and Escherich. They can be cultivated from the washed sputum by inoculation upon blood-serum plates.

The weight of evidence would thus seem to indicate that the Czaplewski-Hensel bacillus is the actual cause of whooping-cough, in spite of the failure to induce the disease in animals by experimental inoculation. Walsh has, however, gone a step further in this direction, having been led by the unanimity with which is emphasized the immunity conferred by one attack of whooping-cough to subsequent attacks, to undertake serum-treatment; and the subcutaneous injection of blood-serum from individuals who had previously recovered from the disease was followed by distinct amelioration in the symptoms. The experiences recorded are insufficient for definite conclusions, but they at least justify further observation along similar lines.

ECHOES AND NEWS.

NEW YORK.

Craig Colony for Epileptics.—This admirable institution is now caring for 615 epileptics and hopes to take care of 720 by January, 1901, and 840 by July 1, 1901.

Woman Physician Sues.—Dr. Anna L. White obtained judgment for $467 against a noted playwright in one of the city courts. The playwright guaranteed the bill for services rendered to a friend.

Railway Surgeons.—The annual meeting of the New York State Association of Railway Surgeons will be held at the Academy of Medicine, New York City, on Thursday, November 15, 1900, under the presidency of Dr. J. L. Eddy of Olean. C. B. Herrick, secretary.

Silver Medal to Dr. Baruch.—At the recent convention of jurors of the World's Fair in Paris, Dr. S. Baruch of this city was awarded a silver medal in recognition of his signal services in bringing about the establishment of free public baths.

Obituary.—Dr. Henry Moreton of 187 Grand Street died in his drug-store at 233 Centre Street October 20, 1900. He was ninety-three years old. He came to this country from England in 1828 with his brother, also a physician.

Dr. John W. Robinson, one of the oldest Wayne County practitioners and prominent in Republican and Masonic circles, fell dead October 20, 1900, of heart disease at his home in South Lyons. He had been County Physician since 1890. He was graduated at the College of Physicians and Surgeons in New York City in the class of 1867.

Dr. Lewis A. Sayre.—At a recent meeting of the Faculty of the University and Bellevue Hospital Medical College the following minute was entered on the records: "The members of the Faculty realize with deep regret their great loss in the death of their late colleague, Professor Lewis A. Sayre, M.D. His long and honorable professional career has shed luster on the calling of his choice and on the medical school to which, at its birth, he plighted his earnest support, and which he sustained with loyal vigor until his death. While bowing in humble submission to the will of Him 'who doeth all things well,' we extend to the members of his family our earnest assurance of sympathy in this their great affliction."

St. Luke's Hospital.—The annual meeting of the Society of St. Luke's Hospital was held last week. The following were elected managers of the hospital: Samuel D. Babcock, George Blagden, Waldron P. Brown, George A. Crocker, Chauncey M. Depew, Theodore K. Gibbs, Anson W. Hard, Woodbury G. Langdon, Benoni Lockwood, George M. Miller, Hoffman Miller, J. Pierpont Morgan, Jr., the Rev. Dr. Henry Mottet, Gordon Norrie, J. Van Vechten Olcott, John B. Pine, Moses Taylor Pyne, Charles Howland Russell, William Alexander Smith, J. Noble Stearns, Stephen Baker, William Fahnestock, and George W. Vanderbilt.

Typhoid in Training School.—Six of the inmates of the Boys' Disciplinary Training School, Eighteenth Avenue and Fifty-sixth Street, Brooklyn, are suffering from typhoid fever. Dr. Frederick A. Jewett, Chief Inspector of Contagious Diseases, was notified of the epidemic and took the necessary precautions to prevent the spread of the disease. The first boy was stricken on Tuesday last, but before the disease had fully developed the other boys became ill. At the school it was said that there was no likelihood of the disease spreading.

PHILADELPHIA.

Dr. Richardson.—Dr. Maurice H. Richardson of Boston was the guest of the Medical Club of Philadelphia Friday evening, October 26th.

Congress of Mothers.—The first annual meeting of the Pennsylvania Congress of Mothers will be held at Lancaster, November 2d and 3d.

University of Pennsylvania.—A vacancy in the medical department is that of Clinical Professor of Genito-Urinary Diseases. This is owing to the fact that Dr. Edward Martin has been elected Clinical Professor of Surgery. Candidates may apply to Rev. J. Y. Burk, 400 Chestnut Street, before November 10th.

Obituary.—Dr. Laurence Turnbull died at his home in this city Wednesday, October 24th. He was born September 10, 1821, in Shotts, Lanarkshire, Scotland, and came to the United States when twelve years of age. He was graduated from Jefferson Medical College in 1845 and soon after became resident physician at the Philadelphia Hospital. In 1859 he visited Europe and made a special study of diseases of the eye and ear. Returning to this country, he published a work on the "Use of the Ophthalmoscope," the first in America. His numerous studies on diseases of the eye and ear are known the world over.

Epidemic of Diphtheria.—Diphtheria has reached Camden and a number of cases are reported. A former coroner states that the disease is of the most malignant type.

A Hygienic School.—At the Holman School for Girls, a college preparatory institution, the individual drinking cup for each pupil, as well as germ-free water, is in use. Systematic muscular exercise is considered a necessary concomitant of study.

Philadelphia Hospital.—The Bureau of Charities has appropriated $130,000 for the erection of new buildings at the Almshouse. The insane department will be enlarged and a building erected for the treatment of infectious diseases.

Statue Purchased.—The Fairmount Park Art Association has purchased the equestrian statue, "The Medicine Man," by Dallin, for $6000. The statue represents a true type of the American Indian doctor and will be an interesting addition to the statuary of the Park.

Druggists Prosecuted.—The State Pharmaceutical Examining Board is waging determined war against violators of the statutes. Over 200 informations have been made in Pittsburg. Detectives report that State laws have been disregarded in so many instances as to leave only a small percentage of the druggists in the State blameless.

Anesthesia Accompanying Bell's Palsy.—At the Neurological Society, October 22d, Dr. J. Hendrie Lloyd exhibited a patient, a young woman, who had Bell's palsy of the right side. Accompanying this was complete anesthesia of the region supplied by the fifth nerve of the same side. The anesthesia was thought to be hysterical in origin rather than an extension of the pathological condition from the seventh nerve.

Smallpox.—Three new cases of smallpox were reported last week. Each case was in a different ward. The disease was well developed, but of a mild type. An unusual point is that all three cases are whites, every other patient in the city since last spring having been a colored person.

Application for Hospital Charter.—The Ogontz Hospital for the Insane has applied for a charter. This institution is intended to relieve the overcrowded condition of the Norristown Hospital.

Quarantine Improvement.—The State Quarantine Board has planned several improvements at the station at Marcus Hook. A detention barracks to accommodate 400 patients will be built, a tug for boarding vessels will be provided, and also a floating disinfecting plant.

Dr. Thomas Addis Emmet.—This distinguished gynecologist operated in the clinic of Prof. E. E. Montgomery at the Jefferson Hospital October 23d. He demonstrated his operation for repairing a complete laceration of the perineum and gave a practical talk upon laceration and its prevention during labor. In repairing lacerations Dr. Emmet prefers silver wire sutures, as they act as splints to the parts involved.

New Litters for National Guard.—The officers of each medical corps of the First Brigade, N. G. P., have been presented with two litters, the invention of Mrs. F. E. Chadwick, wife of Captain Chadwick, U. S. N. These carriers are peculiarly adapted for service on the battlefield, presenting the form of a hammock-chair. It is thought that the carrier can also be suspended between two horses and thus be utilized by mounted men.

Pure Milk for Infant Feeding.—The Commission appointed by the Pediatric Society in 1899 has recently made an interesting report. The Commission issues certificates to dairymen after examination of the milk, utensils, cows, etc., has been made by an expert and found to reach a certain standard. Two dairies have obtained this certificate. Others are being improved in order to reach the standard. This method appears to appeal to the business instincts of the dairymen and to be productive of more good than the endeavor to enforce laws. The report emphasizes the appeal made by Dr. Stengel, a member of the commission, at the meeting of the State Medical Society. That appeal was for the appointment of similar commissions by all local medical societies.

State Examinations Again Prominent.—The daily paper which was prominent in investigating the fraudulent examination of 1899 has come out

with a statement regarding the examination of last June. The claim is made that nearly 10 per cent. of the candidates who were granted licenses at that time failed to attain the necessary average. When the members of the Board met and found that the marks on the individual papers did not reach the required total, some of them were raised or the general average was raised. This was done because the political or personal "pull" of these certain candidates demanded that they pass. The allegations of the paper are presumably true, as it is known that candidates for license have been told by political friends that if they are doubtful of the result they will see that the candidates pass. This is another argument in favor of practical examinations instead of, or in conjunction with, the written ones.

CHICAGO.

Quarterly Medical Examination.—The regular quarterly medical examination by the State Board of Health closed October 11th. Forty-one persons took the examination, 27 of whom were candidates for physicians' certificates, 8 for certificates of midwife, and 6 were classed under the head of "other practitioners."

The Fenger Banquet.—It is said that more than 130 medical societies have thus far appointed representatives to attend this banquet. The President of the American Medical Association, Dr. Charles A. L. Reed of Cincinnati, Ohio, will act as toastmaster.

Free Care for Epileptics.—The Illinois Home for the Treatment and Care of Epileptic Patients is the only institution in the State where the treatment of these unfortunates is free. The object of the home is the establishing of an epileptic colony and the erection of a building for this large class of patients, with farms, workshops, a theater, reading-room, gymnasium, and equipment for restoring the mental faculties of curable epileptics, and to give a miniature world to incurable epileptics. Incarceration of epileptics in insane asylums and the abuse of persons who fall in a fit on public streets are to be prevented. In receiving and treating patients no exception will be made as to color, creed, race or religion.

Saint Gerard's Hospital.—An institution by this name was dedicated three or four days ago. Dr. J. B. Murphy will be the chief surgeon of the hospital.

Medical Legislation of Illinois State Medical Society.—This Committee has been studying the existing medical laws and the means for their improvement. The Committee sees plainly that it will be unable to secure or maintain the most desirable legislative measures without a more complete organization behind it. Among the questions which are demanding solution in Illinois are a thorough organization of city, county and State boards of health with proper relations to each other; more adequate sanitary laws, especially those relating to schools, manufactories, and quarantine; to secure legislation to protect against tuberculosis and other preventable diseases; to protect against vicious legislation, for example, antivivisection and antivaccination; to protect from blackmailing and to protect against unjust malpractice suits; to secure proper recognition of expert testimony; to protect the sick from quacks and charlatans; to protect and improve the medical practice act and to secure a special board of medical examiners, aside from the Board of Health; to secure proper regulations for the protection of drinking waters, and to aid in securing just and impartial legislation whenever and wherever needed; to secure equitable medical laws throughout the United States, with some practical form of reciprocity between the States; to secure the appointment of reputable and honorable medical men wherever public services of physicians are required throughout the State. The Committee hopes to have hearty cooperation in pushing forward the work along these lines.

Officers of the Chicago Gynecological Society.—The annual meeting was held October 19, 1900, and the following officers were elected: President, Dr. Reuben Peterson; First Vice-President, Dr. E. Lester Frankenthal; Second Vice-President, Dr. Henry Banga; Secretary, Dr. William H. Rumpf; Treasurer, Dr. Addison H. Foster; Editor, Dr. Charles S. Bacon, and Pathologist, Dr. Emil Ries.

Smallpox and Property.—A suit was recently brought against the City of Chicago by the owners of land near the smallpox hospital, opened by the municipal authorities on Lawndale Avenue in 1896, to recover damages alleged to have been sustained by their property in consequence of the proximity of this objectionable institution. The plaintiffs were unsuccessful in the court of first instance and have just been finally defeated in the Supreme Court of Illinois. There was no charge that the City had been in any respect negligent in the care and conduct of the hospital or that it was any more of a nuisance than such an institution must be of necessity. The Supreme Court holds that the erection and maintenance of a smallpox hospital within the limits of a city may be justified in the exercise of the police power of the State, and that there is no difference in principle between the right of a municipality to establish such an institution and its right to build a jail, fire-engine house or calaboose. The City would be liable only for an abuse of discretion in locating such a hospital, of which there was no suggestion in the present case.

Appointment of Dr. Webster.—Governor Tanner has appointed Dr. George W. Webster as a member of the State Board of Health to succeed Dr. R. F. Bennett, who has left the Board to become Superintendent of the Southern Hospital for the Insane at Anna.

The Senn Room.—The Senn room in St. Joseph's Hospital, endowed with $10,000 by Dr. Nicholas Senn, has been opened formally. The room is completely furnished by its donor, and the endowment fund will remain intact for its perpetual maintenance. The room is large and spacious, and is considered one of the best in the institution. The furnishings include a library of 500 volumes. The sisters of the institution are having painted a large picture of Dr. Senn, which will also be given a place in the room. During Dr. Senn's lifetime he will have the privilege of designating patients for the room, who will be cared for without expense.

Medical Inspection of Schools.—One or two members of the Board of Education are opposed to the medical inspection of children who attend the public schools on the ground of expense. Friends of medical inspection, however, are determined that this department shall not be abandoned in order to provide funds for the maintenance of kindergartens or other branches of instruction. Parents who look upon medical inspection as a sort of life-saving station in the public schools are protesting to the Board from all over the city. It is more important that the schools be kept free from epidemics than that the full program of studies be carried out. During three and a half months of the last school year 76,000 examinations were made, and 4539 cases of contagious disease were discovered and excluded from the schools. Since September 17th of the present year 7249 examinations have been made and 510 contagious cases have been excluded. These figures speak volumes for the continuance of the system of medical inspection.

GENERAL.

Wyoming State Medical Society.—At the last annual meeting of this body, held October 9, 1900, at Cheyenne, the following papers were read: "The Treatment of Disease with the Alkaloids," by Dr. S. B. Miller of Laramie, Wyo.; "Periosteal Osteosarcoma of the Upper Extremity of Femur," by Dr. Leonard Freeman of Denver, Colo.; "Enteric Diseases of Children," by Dr. J. B. Wilson of Laramie, Wyo.; "Venereal Disease and Its Relation to Marriage," by Dr. P. Hyrup Pederson of Laramie, Wyo.; "Dysentery," by Dr. E. Stuver, A.M., of Ft. Collins, Colo.; "Minor Surgery," by J. Harvey Young of Rock Springs, Wyo.; "Certain Blood Diseases, with Exhibition of Mounted Specimens," by Dr. J. N. Hall of Denver, Colo.; "Mountain Fever," by Dr. R. Harvey Reed of Rock Springs, Wyo.; "Elbow Fractures and the X-Ray," by Dr. W. W. Grant of Denver, Colo.; "Our Present Coroners' Law; with Some Recommendations Growing out of Experience," by Dr. W. C. Burke of Rock Springs, Wyo.; "Meningitis," by Dr. I. R. Swigart of Laramie, Wyo.; "Our State Laws in Reference to Contagious Diseases," by Dr. R. Harvey Reed of Rock Springs, Wyo. The following officers were elected for the ensuing year: President, Dr. E. E. Levers; First Vice-President, Dr. S. B. Miller; Second Vice-President, Dr. W. A. Jolley; Third Vice-President, Dr. Charlotte Hawk; Secretary and Editor, Dr. J. R. Swigart; Treasurer, Dr. W. L. Wicks. The next annual meeting will be held at Evanston, Wyoming.

Obituary.—Dr. William F. Reilly, an eminent physician of Southern Pennsylvania, died at Carlisle, Pa., October 20, 1900, from stomach hemorrhages, aged thirty-eight years. He was connected with the National Guard of Pennsylvania for eleven years as an assistant surgeon, and served in the Spanish war.

Riotous Medical Students Fined.—The medical students who were arrested for breaking up the meeting of Mr. John Alexander Dowie, the Zionist of Chicago, in London were punished with small fines.

St. Luke's Bethlehem, Pa.—Generous gifts have been announced by Dr. Estes of St. Luke's Hospital, in Bethlehem, Pa., including a fund of $10,000 from former President E. P. Wilbur of the Lehigh Valley Railroad for the support of a children's ward, and a new $20,000 operating ward, to be erected by Samuel Thomas of Hokendauqua, Pa.

The Reformation of America.—We are glad to learn that the *Bristol Medico-Chirurgical Journal* is not responsible for the statement quoted in our issue of September 29, 1900. It was the product of its former editor and had been inserted in a reprint issued by that gentleman.

CORRESPONDENCE.

VENTROSUSPENSION OF THE UTERUS.

To the Editor of the Medical News:

Dear Sir: Your issue of October 6th publishes a description of my method of operation on ligamentopaxis (Round Ligament Ventrosuspension of the Uterus) by Dr. D. Tod Gilliam of Columbus, Ohio, which gives the details of the operation, but does not mention my name.

My method was first published and illustrated in the *Centralblatt für Chirurgie,* August 21, 1897. It was also reported by Dr. C. A. von Ramdohr before the New York Obstetrical Society in the same year, and was the subject of a graduation-thesis at the University of Paris under the auspices of Poirier, Berger, Guyon and Albarran. Garrigues's "Diseases of Women" also contains it, and the *American Journal of Obstetrics and Diseases of Women and Children,* Vol. XLII., No. 3, 1900, gives a description of the original operation and its modifications.

I must assume that all this was entirely unknown to Dr. Gilliam, and that on being informed of the facts he will correct the omission.

Carl Beck.

New York, October 9, 1900.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, October 9, 1900.

THE OUTBREAK OF PLAGUE IN GLASGOW APPARENTLY TERMINATED—MALARIA AND MOSQUITOES—COLLECTION AT THE SOUTH KENSINGTON MUSEUM OF MOSQUITOES FROM ALL THE COLONIES FOR IDENTIFICATION AND CLASSIFICATION—THE SUPPLY OF PURE MILK TO HOSPITALS—THE GENERAL ELECTION—MEDICAL QUESTIONS INVOLVED.

The Glasgow outbreak of plague fortunately seems to have run its course, thanks no doubt to the prompt and vigorous measures taken by the authorities of which I have already informed you. For more than a week no fresh cases have occurred. The total number of cases admitted to hospital is 27, of which 5 have been fatal. Only 8 cases have been severe. Seven were so mild that, but for their association with other cases, the suspicion of plague would not have been aroused. Over 60 persons who have been in association with plague patients have been immunized by subcutaneous injections of Yersin's serum in doses of 10 cc. Of these 2 have exhibited the disease in a very modified form.

The question of malaria and mosquitoes is receiving great attention here. In a previous letter I forwarded you an account of the brilliant and dramatic demonstration of Dr. Manson's theory, which has been carried out with the help of the Government in the Roman Campagna and also in the London School of Tropical Medicine. But in other directions also the Government has been active. In 1898 a committee was jointly appointed by Mr. Chamberlain, the Colonial Secretary, and by the Royal Society to exercise a general supervision over a scientific investigation of the question. An order was issued by the Governors of all the Crown Colonies to have collections made of the different species of mosquitoes and allied insects and to send them to the Natural History Museum at South Kensington for examination and classification. Directions for collecting, mounting and preserving the insects were drawn up by the Museum authorities and distributed to the Colonies. As a result over 3000 specimens have been received and more are coming in every week. The work of identifying and describing the specimens was first entrusted to Mr. E. Austen, the dipterist on the staff of the Museum. But, as he volunteered for active service in South Africa, the work was transferred to another professional dipterist, Mr. Theobald, one of the few men in England who have studied mosquitoes. He is now engaged in the preparation of a monograph on mosquitoes based on the collections in the Museum. The genus *Culex*, which has been shown to be the medium for the transmission of malaria, is represented in the Museum by 22 specimens, 10 of which are new to science. Unlike the *Anopheles*, *Culex* has not a wide distribution in regard to species, although the genus is world-wide. One of the greatest distances between any two localities for the same species is Formosa and the Straits Settlements. Some species of *Culex* have a wide distribution; thus, one species has been sent from the following widely-separated localities: Japan, Formosa, Hong-Kong, Malay Peninsula, India, South and West Africa, North and South America, West Indies, and Gibraltar. As many species are obscure, photographs of the wings and drawings of various parts are being prepared, of which figures will be given in the proposed monograph.

Some interesting experiments have been made at Paisley with a view of ensuring a pure milk supply for the patients in the Infectious Disease Hospital. A new byre has been constructed on the most modern principles and is designed to hold 14 cattle. It is ventilated artificially as well as naturally and is better lighted than the usual run of such buildings. A number of cattle were purchased and submitted to the tuberculin test. Those who reacted were slaughtered, so that only healthy cattle were housed. Especial precautions are taken to ensure purity of the milk. When taken from the cows it is immediately put into cans which are fitted with a lock-and-key arrangement, so that they cannot be tampered with on their way to the hospital. Thus the supply of milk to the patients in an absolute condition of purity is ensured.

The country is now in the throes of a general election and several medical questions are involved in the points before the electorate. Though the medical profession is overwhelmingly conservative, a good deal of dissatisfaction is felt with the outgoing Government. Even the *Lancet*, which, like all old and well-established institutions in this country, in matters political on the side of the things which are (how different was the aggressive radicalism of its younger days), attacks the Government on several points, while carefully guarding itself against pronouncing in favor of either party. "There have been lamentable exhibitions of weakness," it says, "in both the great parties in the state in regard to the greatest questions of medical science." The Government has introduced into the Vaccination Acts an unprecedented individual—"the conscientious objector" and deliberately refused to carry out its promise of a "Revaccination Act." It has thrown away an opportunity for guarding the public from gross injury at the hands of companies posing as medical practitioners. Bills for amending the lunacy laws, improving the position of medical officers of health and a very uncontentious bill for amending the Medical Acts, have failed to pass for the want of interest of the Government in non-political questions. On the highly important Midwife Bill it did absolutely nothing.

A Correction.—Dr. Eugene Wasdin desires to call attention to the fact that in his letter of the 13th inst. in the Medical News, the word opposite was substituted for the word *apposite*.

SOCIETY PROCEEDINGS.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Twenty-Sixth Annual Meeting, Held at Asheville, North Carolina, October 9, 10 and 11, 1900.

The Association met at the Battery Park Hotel under the presidency of Dr. Harold N. Moyer of Chicago.

Adresses of welcome, on behalf of the City and State, and of the local profession, were delivered by the Honorable Theodore F. Davidson and Dr. John H. Williams.

Presidential Address.—Dr. Moyer referred to matters of general interest to the profession. He dwelt at length upon an address which was delivered at the International Medical Congress by the distinguished American colleague—Jacobi, who saw fit to discuss the old code question. The speaker thought it unfortunate that this subject, long since dead, but not buried, should be embalmed in the records of that Congress. As to medical societies, there cannot be too many of them. In no other country are these societies so numerous as in America. They are usually well attended. In foreign countries these societies are for the few; in this country they are for the many, and it is to their collective voice, speaking in no uncertain tones, that the profession owes the uplifting of medical education.

Medical Legislation.—The passage of medical acts has been urged by the medical profession, and physicians have been distinctly misunderstood in their attitude toward such legislation. Legislators feel that in some way the medical profession wishes to put a fence around the practice of medicine that physicians inside may fatten upon it. This is not true. Physicians do not urge the passage of medical practice acts for their personal aggrandizement, but simply to protect the people, to prevent the illegal practice of medicine by unqualified persons and by quacks.

Specialism.—If anything can be said in criticism of the medical profession in this country it is the overweening inclination toward specialism. A physician should spend several years in general practice before adopting a specialty. Specialism has done many good things for medicine, but practitioners should see to it that it is not overdone. If a physician wishes to acquire a broad general culture, it can only come from general practice. The selection of a specialty should, like matrimony, come naturally and without being forced.

Abdominal Versus Vaginal Hysterectomy.—Dr. H. O. Walker of Detroit, Mich., read this paper. He said that the question of the best approach surgically to the uterus and adnexa has not been settled. Cancer of the uterus is not an infrequent cause of death in women. The question of recurrence of cancer of the uterus is very important and is immediately connected with the method of its removal. The manner of recurrence of cervical carcinoma is either by extension into the broad ligaments, from the vagina downward and other contiguous parts, as the bladder and rectum, and occasionally to the body of the uterus, or by metastases through the lymph-channels and by distinct direct implantation. The surgeon should be governed by the method of operation which will offer the best advantages in guarding against recurrence of the disease, and in order to illustrate this the author reported two interesting cases, one of which was a vaginal, the other an abdominal, hysterectomy. The report of one case showed what he could not have done by the vaginal method; the other portrayed what he could have done better, more safely and more surely by the abdominal method. All things being equal, the abdominal route offers advantages that do not pertain to the vaginal route. (1) The surgeon is better able to see what he is doing. (2) He is much better able to control hemorrhage by the abdominal than by the vaginal route when he is working in a dark cavity. (3) The danger to the ureters is minimized, and, if injured, the opportunity for repairing them is better. (4) The prevention of sepsis is more certain by the abdominal than by the vaginal route, aided in the first instance by the Trendelenburg posture.

Cancer of Uterus and Treatment.—This paper was contributed by Dr. R. S. Sutton of Pittsburg, Pa. Cancer operations should not be recommended as curative, but as palliative and therefore useful. Total vaginal extirpation of the uterus, at or after the time of the climacteric, should find a place as prophylactic treatment against cancerous disease. The treatment for existing cancer of the uterus has probably reached its complete evolution. With reference to the question of prophylaxis, the average age of patients operated on was forty-three years and a fraction, and it was claimed that, if these patients had all been subjected to total vaginal extirpation at the average age of forty years, all of them would have escaped cancer of the uterus. According to his own statistics, but 4 per cent. of the cases would have died; whereas nearly 100 per cent. of these cases did die within a period of two or three years after operations for cancer. Greater attention should be given by physicians at large to the early repair of lacerations of the cervix and to painstaking observation and consideration of that train of symptoms preceding and leading up to the development of uterine cancer. He unequivocally recommends radical surgical treatment in all such cases, and clearly announces that if the number of cases of uterine cancer and consequent mortality in the future is to be diminished it must be done in forestalling the disease.

Dr. Edward W. Lee of St. Louis, Mo., favors the abdominal operation in a large majority of the cases. He believes it is easier to perform; the operator can see what he is doing; he has a more perfect control of the tissues, and can do a more thorough operation.

Dr. Chauncey D. Palmer of Cincinnati, O., said that until the past few years the vaginal method was preferred to the abdominal. The causative relation between laceration of the cervix uteri and cancer of the uterus is so clearly defined that its importance ought to be recognized by all physicians.

Dr. J. Wesley Bovee of Washington, D. C., mentioned three classes in which vaginal hysterectomy for cancer of the uterus, with the removal of such other structures as may be involved, is advisable. In very feeble patients, who are not able to stand a prolonged operation, he favors the combined method advocated by Ries, Clark, Werder, and others. The combined operation has been done by him in thirteen cases, all of whom are living, with two recurrences.

Dr. A. H. Cordier of Kansas City, Mo., said that in cases in which there is extensive involvement of the cervix by the cancerous process, implicating the bladder and rectum, his patients have been much benefited by thoroughly curetting the cancerous mass, then using the Paquelin cautery, and packing the parts with carbide of calcium. Along with this treatment he uses the old Goodell vaginal injection of permanganate of potash.

Dr. William F. Barclay of Pittsburg, Pa., said that the general practitioner is to be censured to a certain extent for not referring cases with cancer of the uterus early enough to specialists. For years he has made it a rule, when in doubt as to the diagnosis of disease of the uterus and where there was complaint on part of the patient, to refer the case to a specialist, and he has been satisfied with the result. The earlier operations are done for this disease, the greater the prospect of prolonging life.

Post-Operative Internal Hemorrhage.—A paper on this subject was read by Dr. A. H. Cordier of Kansas City, in which he drew the following deductions: (1) In diagnosticating post-operative hemorrhage the history of the patient will aid much. (2) Symptoms of shock and hemorrhage are very similar. (3) In suspected cases the cutting of a single stitch in the incision will tell. (4) In cases in which bleeding is anticipated a tube should be used. (5) The surgery must be quick and decisive in these cases. (6) Large quantities of normal saline solution will save many patients. This should be used both per rectum and into the veins. (7) Strychnine, belladonna, etc., will not control bleeding from the uterine or ovarian artery any better than from the radial or temporal. (8) The surgeon should do what his surgical conscience tells him is right.

Intermittent Hydrops of the Knee.—Dr. George W. Cale of Springfield, Mo., reported the case of a woman, forty-five years of age. Her trouble began five years ago. There was no history of injury. There was a rapid accumulation of fluid in the left knee-joint, which, however, was not painful. This would disappear in from one to four weeks, with or without treatment. The disease would recur at periods varying from one to six months.

Ventral Hernia Following Laparotomy.—This paper was read by Dr. E. Brindley Eads of Chicago, Ill. The occurrence of ventral hernia as a sequence of abdominal section is so common that it should command thoughtful consideration. The author urged the adoption of those methods which personal experience has demonstrated to be of the greatest use, both immediate and remote. As intact innervated muscular fiber is the only safeguard against hernia following laparotomy, the first rule is to make the abdominal incision parallel, or nearly parallel, with the direction of the motor nerves, and of the most important muscular fibers supplied by these nerves. In considering the incision the following points must be taken up: (1) The length is largely dependent upon the thickness of the superficial fascia; it must be sufficient to allow free access to the muscles whose functional integrity is essential to success. (2) The length must be relatively greater than when muscular fibers are to be separated instead of divided. (3) It must vary with the pathological condition. (4) An opening of sufficient size must be secured for thorough exploration and to obtain the requisite degree of precision and rapidity in manipulation. (5) A long incision through the skin and superficial fascia does not predispose to hernia. (6) It lessens the mortality by providing ample space for the protection of surrounding viscera. (7) It lessens shock by diminishing the time required for the operation, and also the duration of the anesthesia. Several incisions were mentioned. The difficulties he has experienced in reaching the appendix through the McBurney incision in acute suppurative cases of appendicitis has caused him to devise another method of approach in a more dependent part. This incision overlies the outer border of the cecum and leads directly to the appendix. It is slightly curved outward and downward, crossing an imaginary line drawn between the anterior superior iliac spines. The center of this curve is from an inch to an inch and a half to the inner side of the right superior iliac spine. The skin and superficial fascia are incised for about two inches. This freely exposes the aponeurosis of the external oblique, which is separated by means of the dry dissector, or the handle of a scalpel, in the direction parallel to its fibers and well retracted. This brings into view the transversely arranged fibers of the internal oblique, and transversalis muscles, and the twelfth abdominal, ilio-hypogastric, and possibly the ilio-inguinal nerve, which are in turn retracted in order to reach the transversalis fascia, which, together with the peritoneum, is divided transversely. The advantages gained by this incision are: (1) It provides easy access to the diseased area. (2) It enables the operator accurately and securely to protect the peritoneal cavity from infection. (3) It lessens liability to breaking down the inner limiting wall of adhe-

sions. (4) It affords a better opportunity to open the abscess cavity from the outer side. (5) It favors drainage. (6) It has not been followed in the author's experience either by appendicular fistula or post-operative hernia.

Gangrene of Scrotum and Penis.—Dr. E. H. Richardson of Atlanta, Ga., narrated the history of a case which showed the initial lesion to have been an abrasion of the skin near the os pubis, with probable infection with the erysipelatous cocci at this point, and later a mixed infection from the streptococcus of gangrene, terminating in the destruction by the gangrenous process of the entire integument of the penis and of three-quarters of the scrotum. A plastic operation was made, with the result that the integument of the penis and testes was preserved. The patient made a perfect recovery.

Tracheloplasty.—Dr. Henry P. Newman of Chicago read this paper. He calls attention to the great importance of the function of the cervix uteri in relation to disease in women. In former times cervical lesions were recognized as a fruitful source of gynecic evils, and many operations and instruments were devised for their correction. Emmet's trachelorrhaphy, once so popular, has ceased to be adaptable to the needs of to-day in repairing cervices. Dr. Emmet, in conceding this himself and offering amputation as a substitute, states that the great advance in the obstetrical art and the methods of caring for a lacerated cervix in labor have altered the character of surgical pathology. The author finds the indications for plastic work upon the cervix still sufficiently widespread to justify the presentation of a new method of operating. This he calls tracheloplasty or plastic work designed not only to restore normal contour and relation, but to reestablish proper function. The distinctive features of the method are the use of a specially designed knife, the shape of the flaps in the anterior and posterior lips of the cervix, clean, smooth-cut surfaces, accurate approximation of flaps, the certainty of restoring the proper lumen of the canal, and the simplicity of the after-treatment. Neither tracheloplasty, nor any one operation of the kind, should be relied on to correct all the ills which accrue from lacerations in childbed. It is frequently necessary to do such simple work as shortening the round ligaments or suspending the uterus, when there is a displacement of the uterus; divulsion and curetting when disease has extended to the endometrium above; repair of the pelvic floor when, through relaxation or trauma, there is a hernial condition of the rectum, bladder, vagina, or superimposed viscera; sometimes even the opening of the abdomen for plastic work, or resection of pathological conditions of the ovaries, tubes, etc. Any one or two of these accessory operations may be necessary to restore the patient, although the disease or deformed cervix may have been the essential, perhaps the sole, etiological factor in the case.

Middle-Ear Disease and the Cranial Cavity.—Dr. O. J. Stein of Chicago read this paper and pointed out the necessity of recognizing the importance of possible intracranial complications in every case of middle-ear disease. The various avenues of infection were dwelt upon at length, these being illustrated by beautiful drawings and specimens. The symptomatology of intracranial phlebitis, thrombosis and abscess was discussed, and several instructive cases reported. In connection with this paper Dr. J. Holinger of Chicago gave an interesting stereopticon demonstration.

Address in Medicine.—This was delivered by Dr. I. N. Love of New York. He selected for his subject "Nutrition and Stimulation." Continuance of life, beginning with the original protoplasm, the cell, depends upon proper nourishment. The proper nutrition of the new being, from the very beginning, prior to birth, should be carefully considered. The entire scheme of tissue-building, of repair, of maintenance of the mechanism of the human body involves not only nutrition, but perfect elimination, and the two together are expressed in the term metabolism. Interrupted metabolism tends toward organic disease and, finally, death. Perfect metabolism means perfect health. Stimulants are of value, if used in the right way and at the right time. In the healthful condition they are not needed. Coffee and tea are essentially domestic pleasures, and, while seemingly harmless, they are potent whippers-up of energy and should be used with great care.

The Treatment of Perirectal Abscesses.—Dr. John L. Jelks of Memphis, Tenn., said that rectal abscesses, when properly treated, are not as serious as when it was the practice to use poultices and await pointing. These abscesses need not result in fistulæ, unless they are the result of malignant diseases, as tuberculosis, cancer and syphilis. Simple incision and drainage of these abscesses do not get rid of their walls, hence this barrier to infection remains as an irritant and causes suppuration. In many cases the abscess-wall becomes calloused, and all efforts to establish granulation are futile. When one is able to elicit fluctuation, free opening and irrigation may result in cure. With a sharp, irrigating curette all of the abscess-wall should be removed and the cavity thereby converted into a surgical wound. Formalin solution is best for irrigating these cavities and they should be packed with iodoform gauze. After thus treating these cases no further suppuration need be expected. Superficial abscesses should be dealt with in the same manner; or they may be frozen and excised as the surgeon would a tumor. They are, when otherwise treated, liable to infect deeper structures. Local anesthesia will suffice, for curettage can be properly practised with it.

Enucleation for Hemorrhoids.—Dr. J. Rawson Pennington of Chicago contributed this paper, which was profusely illustrated. He gives a cathartic two nights before the operation, a saline the following morning and a bath, and colonic flushing the night before. The next

morning he gives an enema of from one-half to one pint of cool water, and operates two hours later He emphasizes the importance of carefully examining the entire rectum. He grasps each anal quadrant at the muco-cutaneous junction with a pair of forceps; the anus is everted and the internal tumors exposed. Seizing the forceps attached to the posterior quadrant, he fully everts it, and with a pair of scissors curved on the flat cuts off the redundant membrane only, which is usually about one-third or one-half of the uppermost part of the hemorrhoidal node. This permits the blood in the tumor to escape. All of the angiomatous tissue is carefully removed, when the remaining wall collapses. Each quadrant in regular order is treated in a like manner. A stream of hot sterilized water flows continuously over the field during the operation. Spurting vessels, if any, are caught with forceps and thoroughly twisted. Should this fail to control hemorrhage, he ligates the vessel. After the operation he introduces a rubber-covered tampon. The advantages of this method are: There are no stumps to slough; no nerves are caught and squeezed; nor are the nerves and tissues burned to a crisp, as when the clamp and cautery are employed; the formation of stricture is obviated. The patient is given a cathartic, and the tampon painlessly removed at the end of forty-eight hours. There is no pain nor bleeding with the movement of the bowels. After the bowels have moved, the patient is instructed to keep the stools soft for two or three weeks by taking compound licorice powder or Apenta water, the latter being very palatable and effective. He has performed this operation in fifty cases, with more satisfactory results than he has obtained by any other method.

Obstipation.—Dr. Sterling B. Taylor of Columbus, O., read this paper. Obstipation was defined, and a comparison of obstipation, constipation and costiveness made. The causes of obstipation were dwelt upon and classified. Hypertrophy of the rectal valve was emphasized as the usual cause of obstipation. The essayist defended the views of Martin and his method. The symptomatology of the affection, palliative and radical treatment were discussed, the author closing his paper with the citation of several cases.

Tuberculosis of the Spine.—Dr. Alexander C. Wiener of Chicago contributed a paper on this subject. He made a plea for early diagnosis before deformity is noticeable. Extension and hygienic treatment are essential in avoiding complications, such as paresis and gravitation abscess. He exhibited a specimen which illustrated the possibilities of forcible correction of the spine. He narrated cases of psoas abscess in which he had effected a cure with injections of concentrated carbolic acid.

Treatment of Cervical Lymph-Nodes.—Horace H. Grant of Louisville read this paper. The purpose and function of the lymphatic glands were dwelt upon. The author showed how they may be rendered useless and harmful by disease and disintegration. He pointed out the limitations of medical and expectant treatment, and outlined the indications for the various surgical procedures.

Fulminating Appendicitis.—This was the subject of the Address in Surgery delivered by Dr. Charles A. Wheaton of St. Paul, Minn. He said that every case of appendicitis is and by rights should be considered surgical, because the surgeon's training specially qualifies him to best interpret the meaning of the symptoms encountered. Every case of so-called fulminating appendicitis should be operated on as soon as its distinctive characteristics are known. High temperature and accelerated pulse, associated with local pain and rigidity, are strong presumptive evidences of malignancy in the attack, and if associated with vasomotor disturbances are practically proof positive of perforation. The surgeon who refuses the only chance that drainage may give even the most desperate cases is false to himself and fails materially in discharging his obligations to his patient, obligations which the patient has a right to expect at his hands. A puncture in the median line, in the loins, or in a woman in the posterior cul-de-sac, under local anesthesia, does not add to the danger of the condition, and it materially aids nature in the awful up-hill fight. In short, in every fulminating case, operate first, and philosophize afterward.

Subarachnoidean Injections of Cocaine.—Dr. Carl H. Andersen of Chicago spoke on the use of such injections in operating below the diaphragm. He referred to the work of Tuffier, Bier, and others in this comparatively new field, saying that sufficient credit had not been given to Leonard Corning as the originator and adviser of this method of anesthesia. He described its technic, which is substantially that outlined by Tuffier, and reported six cases in which he had resorted to the method. (1) Hydrocele, with vague history. Patient, colored, twenty-eight years of age, strong and healthy. Subarachnoidean injection of 15 minims of a two-per-cent. solution of cocaine. Anesthesia complete. On opening the scrotum sarcoma of the testicle was found and removed. Ninth day after operation patient died from pulmonary embolism. (2) Varicose veins of the leg. Injection of 8 minims of a two-per-cent. solution of cocaine. Anesthesia lasted five hours and ten minutes. No pain during operation. Perfect recovery. (3) Trachelorrhaphy. Cocaine anesthesia. As soon as operation was finished the patient fainted and remained in that condition for two hours. Under strychnine and salt water per rectum, she rallied and recovered. (4) Amputation of toe in a man, seventy-two years of age. Seven minims of a two-per-cent. solution of cocaine injected. Uninterrupted recovery. (5) Operation for suppurative appendicitis. Patient, woman. Operation performed at 10 A. M.; at 2 P. M. patient showed symptoms of medullary irritation, pain in the back, and severe headache. The patient had a

terrific headache for several days after the operation. (6) Version and use of forceps. At the suggestion of Dr. Harold N. Moyer, Dr. Andersen injected 16 minims of a four-per-cent. solution of eucaine B in this case, with very satisfactory results. Patient suffered no pain whatever. Eucaine B can be perfectly sterilized by boiling. Dr. Andersen spoke of the difficulties attending the sterilization of cocaine, and outlined a method by which this can be accomplished. He regards lumbar puncture as a serious operation, and urged practitioners to be exceedingly cautious in employing it. These cases were reported for the express purpose of warning the profession that the method is far from harmless, and if it is employed indiscriminately it will lead to disastrous consequences.

In the discussion, Dr. Harold N. Moyer said that if asked in regard to the use of this method of anesthesia, he would say, do not use it. No surgeon should undertake it unless he has a well-equipped laboratory. The method is at best in its experimental stage, and further research and experiments should be carried on in well-equipped clinics until the possible dangers of this method are better and more clearly understood. Among the dangers are the toxic properties of the cocaine. A four-per-cent. solution of eucaine B can be used with absolute safety. It is about one-third as toxic as cocaine, and one-half as anesthetic as cocaine, but it can be absolutely sterilized. The danger of infection from such injections is considerable and should not be overlooked. As to the remote dangers from this form of anesthesia, cases have not been observed sufficiently long to enable surgeons to say whether or not there are such dangers.

Tuberculous and Purulent Hip-Joint Disease.—Dr. A. M. Phelps of New York said that all abscesses, tuberculous or purulent, should be opened as soon as the diagnosis is made for the purpose of exploration; secondarily, for drainage and for any surgical procedure which may be deemed advisable. Excisions should be performed when the acetabulum is extensively diseased, the diseased tissues removed, and the joint thoroughly washed out with pure carbolic acid, then with pure alcohol, and finally with a two-per-cent. solution of carbolic acid, and as large a drainage-tube of glass as the wound will take should be inserted. Through this large drainage-tube the packing for drainage purposes can be made. The large glass speculum enables the operator to watch every pathological change which takes place. It keeps the soft parts widely separated and prevents their union until after the bone has granulated up and healed. It enables the operator to dress his patient without doing violence to the granulating surfaces of the wound and inflicting unnecessary pain. All rubber drainage-tubes should be entirely discarded, as they are filthy, collapsible, and are a source of infection. The carbolic acid is absolutely neutralized by the action of the alcohol. Local carbolic poisoning, and even when the drug is taken internally, is neutralized by the action of the alcohol.

Pulmonary Tuberculosis in Infancy and Childhood.—By Dr. Frank P. Norbury of Jacksonville, Ill. This disease is not rare in children. Heredity is of etiological importance, but it has lost its prestige and it has been shown that infection is the main etiological factor. The mode and route of infection are important considerations. Northrup, Carr, and others have shown that tuberculosis starts most frequently in the thorax. Pulmonary affections, such as whooping-cough, influenza, etc., create favorable conditions for infection. Enterocolitis and gastro-enteritis create portals for intestinal infection. Milk is a source of infection. Tuberculous meat, too, is a source of infection. Differential diagnosis from bronchopneumonia can only be made by laboratory methods. Acute miliary tuberculosis and bronchopneumonic tuberculosis are most frequently found in infants and children. The complications are meningitis, empyema, and involvement of bones. The prognosis is grave in almost all cases, but lesions of lungs may heal under favorable conditions. With reference to treatment, prophylaxis during infancy should include attention from birth, if mother is tuberculous; also good hygienic, open-air treatment; climatic change, when possible. The symptomatic care should be the same for children as for adults. Good nutrition should be maintained and as little medicine as possible given. Creosote and simple tonics are recommended.

The Physician as a Sanitarian.—Dr. Hugh A. Cowing, of Muncie, Ind., discussed preventive medicine; hygiene of infection; the physician as a factor in the spread of infection; the physician and the health officer; health legislation, and the physician and the public schools.

Philosophy of the Science and Art of Medicine.—By Dr. William F. Barclay of Pittsburg, Pa. True and false philosophy should be appropriately applied to results obtained in rational conclusions. The philosophy of medicine is the comprehension of the truth in the investigation of the science, enabling one to arrive at rational conclusions in the study of physical laws which govern organized matter in normal and pathological condition.

Asthma.—Dr. B. Alexander Bate of Louisville said that modern opinion seems to regard asthma as a neurosis of the pulmonary plexus due to arthritism. In bronchial asthma uric acid in the blood so alters nutrition as to cause a neurosis, thus inducing hyperesthesia and engorgement of the bronchial mucosa, spasmodic contraction of the muscular fibers, and the various manifestations of metabolism. Asthma frequently alternates with such diseases of the arthritic diathesis as neuralgia, migraine, angina, and gout. Clearing the blood of uric acid has relieved asthma only to be followed by gout, as the uric acid was precipitated into the tissues. Asthma may be said to belong to the class of uric acid diseases due to the effect of high arterial tension in con-

tradistinction to those produced by precipitation of urates into the tissues. The attacks come on most frequently when the blood is loaded with uric acid during the alkaline tides. The causes of asthma were divided into two classes: First, the systemic or essential cause—the arthritic diathesis. Second, the local or exciting cause of the attack. The first of these is perhaps present in every case. Modern methods of treatment have been able to cut short the attacks in most instances and often to prevent their return. After the removal of the exciting cause the treatment consists in the use of such remedies as overcome arterial tension by freeing the blood of uric acid. The treatment of the interval consists in the use of such drugs as eliminate uric acid from the system, and the adherence to such a diet as permanently keeps down arterial tension.

Inebriety and Medical Treatment.—Dr. T. D. Crothers of Hartford, Conn., said that inebriety is a self-limited and largely curable neurosis. The desire for drink is symptomatic. The real causes are central nerve-irritation, exhaustion, poisoning, and starvation. Each case requires special means and measures, particularly adapted to meet the conditions present. The family physician as well as the specialist should treat these cases successfully.

Clinical Application of Suprarenal Capsule.—Dr. W. H. Bates of New York regards the aqueous extract of the suprarenal capsule as the most powerful stringent, hemostatic, and heart tonic known. It lessens congestion of the eye and of other organs. The extract is not irritating or poisonous, and, unlike other powerful drugs, is never contraindicated.

Purgative Mineral Waters.—Dr. Edwin Rosenthal of Philadelphia discussed this subject. He spoke of natural and artificial mineral waters; simple, thermal, common salt, or muriated waters. He dwelt upon the waters mostly met with in commerce, spoke of their chemistry, names, mode of action, uses, method of selection of a special purgative water, etc.

The Law and the Surgeon.—Dr. Dudley S. Reynolds of Louisville, Ky., said that a surgeon must possess a reasonable familiarity with the science of his profession; he must exercise reasonable skill for the locality in which he practises, and must devote due diligence and care in attending to his patient. If the patient declines to submit to treatment, the surgeon does not abandon the case at once, he assumes liability for the result of failure to do that which in his judgment was best for the relief of the patient.

Differential Leucocytosis.—Dr. L. H. Warner of Brooklyn, N. Y., read this paper. Experiments in recent times have given us a better insight into leucocytosis. It has been demonstrated to be due to three causes—digestion, inflammation, and infection. Physiological and biological experiments have proven that by means of medication a true picture of leucocytosis may be produced, but which in reality represents leucocytodiuresis, a condition very desirable in the treatment of disease and a recognition of which is of the greatest value when hematology is called upon to aid in arriving at a correct diagnosis.

Election of Officers.—The following officers were elected for the ensuing year: President, Dr. A. H. Cordier of Kansas City, Missouri; First Vice-President, Dr. Charles F. McGahan of Aiken, South Carolina; Second Vice-President, Dr. Charles L. Minor of Asheville, North Carolina; Secretary, Dr. Henry E. Tuley of Louisville, Kentucky, re-elected; Treasurer, Dr. Dudley S. Reynolds of Louisville, Kentucky, re-elected. Put-in-Bay, Ohio, was selected as the next place for holding the meeting; time, September 10, 11, and 12, 1901. Dr. J. C. Culbertson of Cincinnati, Ohio, was selected as the Chairman of the Committee of Arrangements. The meeting ended with a banquet at the Battery Park Hotel given by the Buncombe County Medical Society.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON MEDICINE.

Stated Meeting, Held Tuesday, October 23, 1900.

John H. Huddleston, M.D., Chairman.

The paper of the evening, read by Dr. Alfred Meyer, was entitled "The City and Its Consumptive Poor; A Plea for a Municipal Sanatorium Outside of the Corporate Limits." (See p. 639.)

Financial Difficulty.—The discussion of the paper was opened by Dr. John B. Cosby, Commissioner of Health of New York City. He said that the need for an institution for incipient cases of tuberculosis such as Dr. Meyer suggested in his paper is very evident. The practical difficulty in the way is the provision of the sum of money necessary for the purpose. The $350,000 proposed by a bill passed in the last Assembly is far beyond anything that city financiers at present think themselves in a position to allow. There remains this question with regard to any appropriation made: Shall it be used by the Board of Health in the furtherance of work now in hand—the purifying of the tenement district from tuberculosis and the like—or shall it be employed to found a special hospital for incipient cases? If an amount sufficient for a hospital cannot be obtained, at least an increase of the present means of fighting tuberculosis should be allowed.

The Present and Immediate Future.—John W. Keller, Commissioner of Charities, sent a note of regret for his absence and some remarks on the subject, which were read by the secretary. He said that at present there is not sufficient room in the charitable institutions of the city to provide places for all the cases of advanced tuberculosis that apply for care and treatment. Within the next year, however, the provision of accommodation for the City's insane in the Manhattan public hospital will leave to the Board of

Charities the whole of Blackwell's Island now given up to the insane. Three buildings will be vacated there, in healthy locations on the East River and separated from one another. These will provide very suitable quarters for a great many additional tuberculous patients. This will obviate the necessity for special provision by act of legislature in the immediate future. The death-rate from tuberculosis in the public institutions of New York during the last year has not been encouraging. A mortality of over 33 1/3 per cent. shows the need for more suitable quarters and care. This mortality will undoubtedly be distinctly lessened when Blackwell's Island will be available for the City's consumptive poor. Personally, Commissioner Keller is heartily in accord with the movement to provide for incipient cases of tuberculosis, but he feels that advanced cases which are so liable to be fruitful sources of contagion need our most solicitous care at once.

Care of Consumptives.—Dr. Hermann M. Biggs said that seven years ago he drew up for the city authorities a scheme for the proper management of consumptive cases. He pointed out that three things are necessary: (1) A receiving pavilion at Bellevue Hospital where the cases could be properly diagnosed and where the tuberculous patients would not be a source of danger to others. (2) The setting apart of special wards for advanced cases. (3) The establishment of a cottage sanatorium for incipient cases. It was suggested that the neighborhood of Central Islip, Long Island, where the City owns some land, would be a suitable place for this cottage sanatorium. The scheme was approved by the Commissioners of Charities, especially by President Porter, but there were no funds available for its accomplishment. Under Mayor Strong the reception pavilion at Bellevue was begun and this is now ready for occupancy.

Number of Consumptives.—Dr. Meyer has said that there are 30,000 cases of tuberculosis in the city. This is an extremely conservative estimate. There are certainly many more than this. The number of incipient cases is set down as 8000. Dr. Biggs is of the opinion that there are at least 15,000 incipient tuberculosis cases in New York, one-half of whom recover and so, perhaps, form no part of the statistics. In 1897 the notification of tuberculosis was made compulsory. Since then the death-rate from tuberculosis has dropped very markedly. While the death-rate in 1889 was 4.4 per 1000, in New York City, last year it was only a little over 2.8. It seems advisable that the money provided by appropriation for the improvement of present conditions with regard to tuberculosis should be spent rather in preventive medicine than in the care of a few favored ones in a sanatorium.

Dr. John P. Faure, ex-Commissioner of Charities, said that the present movement was in line with other great philanthropic purposes now being accomplished here in New York. Floating hospitals have done much to reduce the death-rate among infants in the city. If the mortality from tuberculosis can be reduced the present generation will accomplish something worthy of itself.

Mr. Frederick Sturgis, Vice-President of the Presbyterian Hospital, said that general hospitals cannot provide places for tuberculous patients. They have no room for them and, moreover, the tuberculous would constitute too great a source of danger for other patients. There is absolute need, therefore, for a special hospital for these patients.

Sanatorium Success.—Mr. Jacob H. Schiff, President of the Montefiore Home, said that the Home had tried the experiment of the sanatorium treatment on a small scale at Bedford Station, Westchester County. This proved so successful that they have tripled the size of the sanatorium and now all tuberculous patients are to be sent there. They are, however, unable to cope with the large problem of tuberculosis and think the State and City should take up the question.

Mr. Savage, of Roosevelt Hospital, said that dispensary cases of tuberculosis, *i. e.*, those living in tenement-houses, are a constant source of menace to those living near them. It is a duty to remove these people just as much as if they had scarlet fever or smallpox.

In closing the discussion Dr. Meyer said the present health authorities of New York all favor the sanatorium idea. Even with the additional beds in Blackwell's Island the City will be far from being able to cope with the problem of tuberculosis in our midst. We do not want drastic measures of compulsory segregation, but it is plainly the duty of the City to give its tuberculous citizens the best possible chance for saving their lives and at the same time to protect its healthy citizens from danger of infection.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held Thursday, October 4, 1900.

The President, Wm. H. Thomson, M. D., in the Chair.

Infant Feeding.—Dr. Abraham Jacobi of New York read the report on the artificial feeding of infants which he prepared by request for the International Congress of Medicine at Paris this year. Only an abstract of this report was presented to the Section on Children's Diseases at Paris, and now, by special invitation, Dr. Jacobi read the complete paper. He said that in recent years a great deal of literature had accumulated on the subject of the preparation of food for the infant. Most of this consisted of dictatorial precepts founded on supposedly scientific laboratory investigations rather than on the results of clinical experience. Most of the writers on the subject seem to have overlooked the fact that chemistry is not physiology and that the infant stomach is not a test-tube. Besides this, in Dr.

Jacobi's characteristic way, he said that much of the recent literature on the artificial feeding of infants exhibited the carping spirit so distinctive of ambitious mediocrity. The science of man and of his diseases does not find the solution of its problems in chemical or mathematical formulæ. Certain phases of the recent literature, however, are of great interest and at least suggestive if not of practical value.

Composition of Mother's Milk.—Mother's milk is not the definite compound that some have been accustomed to consider it. The child may thrive on one woman's milk and fail completely to do so on another's. Some standard for the preparation of an artificial food that will more or less resemble mother's milk is needed. A standard is obtained by taking the average of a series of analyses of human milk. The analyses of different examiners have proven, however, rather contradictory. This is not so much to be wondered at, however, if we bear in mind that not only the milk of different women differs, but the milk from the same woman may differ according to her physical condition, according to the amount and character of the food she is taking and even according to her emotional state during a given period. Variations in milk as the consequence of menstruation and of excessive lactation are well known. It has been said that there is more albumin in human than in cow's milk. Whether all of the albumin in woman's milk occurs in the form of casein is not known. Pfeiffer insists that all the nitrogenous substance of milk exists in the casein. This matter is still in doubt. The usual assertions, therefore, with regard to the comparative casein content of human and cow's milk are not absolute. It is known that there is more phosphorus and less sulphur in woman's milk than in cow's milk, also that the inorganic acids and salts of woman's milk are not precipitated as easily from their solution as in cow's milk. It is known that lab ferment produces larger curds when allowed to act upon cow's milk than upon human milk. All of these are important differences between the two substances with regard to their nutritive value.

Phosphorus in Milk.—Nearly all the phosphorus in woman's milk exists in the form of readily absorbable organic compounds. In cow's milk the phosphorus exists in the shape of an organic compound difficult of absorption. This constitutes without doubt one of the great reasons for the frequent development of rickets in bottle-fed babies. Something of the same thing can be said for the iron which exists in milk. There is less sodium in cow's milk and for this reason it is advisable to add sodium chloride to any artificial food whose basis is cow's milk. The necessity for the addition of sodium chloride is emphasized if cereals are added to cow's milk in the preparation of baby food. Zweifel, in the chapter of his new book which treats of rickets and its causes, says that the women of the lower classes in Saxony are accustomed to eat bread that, according to the habit of the country, is made without salt. This has, undoubtedly, according to him, an influence in the causation of the large amount of rickets which is seen in that country. Fortunately for the infant, Nature has permitted considerable latitude as regards the food which may be necessary for a child's nutrition. It is to this fact rather than to any definite knowledge, with regard to the ideal baby food, that is to be attributed the modicum of success the medical profession has had in artificially feeding infants.

Advance in Artificial Feeding.—Just one good step forward in the matter of artificial feeding has been definitely made as the result of these dozens of years of work. This is the heating of the milk—some method of sterilization, Pasteurization or Tyndallization being used. Undoubtedly dirty dairies have been and are still the source of a great deal of disease. Scarlet fever and diphtheria are probably spread more by milk than by any other known means. After water milk is the most serious distributing agent of typhoid fever. The germs get on the hands of those who furnish milk for the market. The bacilli also get into the water in which the vessels are washed. It has come to be realized of recent years that tuberculosis is also occasionally spread by milk. The most serious consideration in the matter is the wonderful rapidity with which microbes grow in milk. A few bacilli find their way into the milk and in twenty-four hours there are millions of them. Only sterilization can protect against these bacterial dangers. Short sterilization is not sufficient and some form of heating is advisable even in winter and in country places where the milk is reasonably fresh. A germ-free milk cannot be obtained. According to the bacteriologists all that is required is that milk shall not contain more than 10,000 germs per cubic centimeter and that none of these shall be pathogenic. It was found in Berlin that some pathogenic bacteria occurred in eighty per cent. of samples of milk obtained in the ordinary course of commerce. Heat to at least 100° C. is necessary to protect against these bacterial dangers, even when the bacteria are not specifically pathogenic. Degeneration of the liver, pancreas and kidney take place as the result of the presence of even non-pathogenic micro-organisms in the intestines. Intestinal irritation produces its effect on the general system, even when the microbes themselves do not find their way beyond the intestinal wall.

Difficulties of Sterilization.—If bacteria contain fat, as does, for instance, the tubercle bacillus, they possess greater resistive vitality than other micro-organisms and require at least 100° C. When microbes occur in fat the same rule holds and the microbes of butter and of rich milk require specially high temperatures for their destruction.

The presence of one-fifth of one per cent. of lactic acid prevents the sterilizing effect of Pasteurization. The presence of lactic acid, however, inhibits the growth of micro-organisms, so

that while it is a disadvantage it is also an advantage. Unfortunately it seems true that when sterilization is conducted at high temperatures a change takes place in the albumin of the milk. At temperatures that fail to destroy the spores of bacilli and that do not affect their toxins milk albumin becomes so changed as to be rendered very difficult of digestion.

Tyndallization.—The only means thus far found to overcome these difficulties in the sterilization of milk is the method invented by Tyndall. This consists of discontinuous sterilization. That is, the liquid to be sterilized is heated several times to a temperature high enough to kill ordinary micro-organisms. In the interval between two sterilizations, microbes that during the first heating were in the resistive spore stage germinate and take up the ordinary bacillary form. These are destroyed by the next heating, and the few spores left in the same way by the third heating. It is now over forty years since Dr. Jacobi first directed that milk for infant's food should be heated several times before use. It is the immortal merit of Soxhlet that he systematized this method of sterilizing milk. It is better that milk should be sterilized by a private family for its own use than that it should be secured from a laboratory which sterilizes it wholesale for commerce. The hay bacillus and Pflüger's bacillus are often found in milk and are especially resistive to heat. Their presence, while not especially dangerous, is undesirable because of certain changes that are induced from the milk. It must be remembered that the membrane formed over milk during the boiling process helps to keep tubercle bacilli alive. Hence the milk should be stirred during the boiling or the scum should be removed as it forms and the boiling continued for some time afterward.

Scurvy.—The idea has gained ground that the sterilization of milk produces changes in it which make it indigestible and so lead to the development of that disease of malnutrition which has become somewhat common of late, namely, scurvy. The American Pediatric Association collected 379 cases of this disease. One hundred and seven of these children had been fed on sterilized milk, while the remainder had been fed in various other ways, a few of them even on mother's milk. It is evident then that sterilized milk is not especially the cause of the disease. Marfan denies all connection between the scorbutic tendency and the use of sterilized milk. He claims that scurvy is always due to overfeeding. Overfeeding, however, has been a failing of mothers from time immemorial, yet in recent years scurvy has become much more common than it was. Dr. Jacobi sees many more cases of it now than he did in the first years of his practice. He is convinced that the increased number is not due to better diagnostic acumen of late years, nor to the fact that the disease is looked for with more care.

Long Duration of Sterilization.—It is probable that whatever influence in the production of scurvy is due to sterilized milk comes from the heat changes produced in the albumin. The proteid material thus becomes inassimilable and the child's nutrition suffers. It has been the custom to think that if heating for twenty minutes did good, heating for an hour would assuredly be of benefit. Some have even recommended the continuation of Pasteurization for from forty to sixty minutes. This is inadvisable and it is from this overcooking that the milk becomes unsuitable to the infant digestion.

Milk Modifications.—Rotch's work in the modification of milk has been most helpful and suggestive. He requires that the cow's milk which forms the basis of the infant's food should come frome large dairies rather than be the milk of one cow. Most infections come from small dairies. The milk should be obtained with the most careful precautions as to cleanliness, should be immediately put on ice and kept thus until ready for use. In order to adjust the proportions of cow's milk, he suggests the separation of the cream from the milk by a centrifugal machine. He then mixes cream and milk in what are considered to be suitable proportions for the given case, diluting where necessary the water or lime-water. Of late he has used barley-water as a diluent. Each infant requires an especially prepared prescription and Rotch has stated that as many as 500 different modifications may be needed for different infants. It is evident that this is a very complex method. It is probable that most infants will thrive on this modified food, but many despite precautions will suffer from mild rachitis and craniotabes. This is because the phosphorus and certain ingredients of animal food are lacking.

Laboratory Preparation.—It is doubtful if the laboratory preparation of milk for infant feeding will ever be a success. This method encourages routine which is just the thing that is not wanted in infant feeding. There are those, moreover, who have seen flies and cockroaches in laboratory bottles. While these insects had doubtless been sterilized in the preparation process in the laboratory, they are not desirable ingredients of baby-food. Laboratory food is besides very expensive. It is not for the poor at all. From three to four dollars a week, or more, is beyond the means of the ordinary family for baby food. It is probable that the separation of milk by mechanical methods that involve over 6000 revolutions a minute, disturb the constitution of the milk. The cream separates and may not again unite. Mice have been fed exclusively on milk and lived, but when the milk was run through a separator and the ingredients mixed again they did not thrive. The reunited ingredients of the milk do not form milk in the true sense of the word.

Milk Sugar.—It is not entirely certain that the milk sugar which occurs in woman's milk is the same as that in cow's milk. Certainly the milk sugar which occurs in commerce is notedly impure. It is probable that for feeding purposes, cane sugar is at least as good. It has been shown that

cane sugar is changed by microbic action into lactic acid. As this is one of the modifications of milk sugar, which is supposed to be of special benefit to the infant because of its inhibitory effect on bacterial growth, one feature of the necessity for milk sugar disappears. In any ordinary cow's milk it is probable that there is enough milk sugar for the infant's nutrition. It is far easier to give too much than too little sugar. It is better to give small amounts of cane sugar than larger amounts of dubious milk sugar. Some milk sugar is absorbed as galactose and glucose, so that the direct use of glucose is not irrational. Marfan gives cane sugar because it is so difficult to obtain pure milk sugar in commerce. Cane sugar should be increased in the infant's dietary whenever the child suffers from constipation. The material makes a simple laxative and does away with the necessity for undesirable drugs.

Fats.—Fats are added by some to cow's milk partly for their influence on the nutrition of the infant and partly because they are supposed to assist the digestion of casein. It is probable that the fat of cow's milk should be reduced rather than increased. In nurslings a great deal of fat is eliminated unchanged. If the amount eliminated becomes excessive, intestinal irritation is set up and a fatty diarrhea is liable to ensue, which still further reduces the amount of fat absorbed by the infant. The fat of asses' milk is low in amount, yet as is well known this agrees very well with children—in fact, better than any other animal milk.

Plain Milk as Food.—In France plain cow's milk is very generally in favor for the feeding of children. In warm weather there is need of diluting the milk and of diminishing the total food taken. There are excellent reasons for high dilution. Babies need much more water as a rule than they are given. It should be given them in their food. It has been objected to this dilution that large quantities of liquids given dilate the stomach. This observation is not the result of clinical experience, but was evidently made at the desk. As soon as the quantity of liquid becomes slightly excessive the child's vertical stomach passes it on and the intestine absorbs it rapidly. Dr. Jacobi has never seen a case of dilatation of the stomach from the consumption of too much liquid, although he is accustomed to give liquids very freely. The lack of sufficient liquid in the system leads to the formation of uric acid infarcts and these predispose to nephritic calculus. Flushing out of the system also avoids irritation of the kidney. Milk if well diluted does not curdle in the thick, indigestible masses that pure milk does. When so diluted it leaves the stomach cleaner, and is liable to give the infant less trouble, for in the infant intestinal indigestion is very important. When infants are given plenty of water there is less loss of weight.

Cereals in Milk.—Of late years the prejudice against the use of cereals in infant's food has gradually been overcome. The dilution of milk with some cereal water, as barley water, makes it much more digestible. It has been said that infants are unable to digest starch, but this has been proved untrue. Heubner found in the infant of two hours, of sixteen days, and of two months, that diastase was present in the parotid. There was none in the pancreas, and pancreatic digestion does not begin until the infant is nearly a year old. The old literature which condemned the giving of starch so vehemently referred to the excessive use, or the exclusive use, of starchy foods. The feces of an infant fed on milk diluted with barley-water contain no fat and very little starch.

Phosphorus in Milk.—In the discussion Dr. Koplik said that the nuclein of cow's milk contains phosphorus, but in a form in which it is frequently not absorbed by the infant. In this respect cow's milk is very different to mother's milk and hence rachitis develops so frequently in bottle-fed babies. Cow's milk must be used, but some simple modification will usually be sufficient and scientific accuracy in the matter cannot be expected. If the infant does not thrive slight changes must be made in the formulæ of modification. Moderately clean and fresh milk can now be obtained and, if on simple dilutions the infant does not thrive, cereals should be added. It is unfortunate that scurvy has been attributed to sterilized milk. Scurvy occurs in any food and is probably due to some pathological process that is interfering with digestion and producing toxemia. There are half a million of sterilized-milk-fed babies and less than 400 cases of scurvy. Scurvy is a curable disease, while affections that come from unsterilized milk are often incurable.

Dr. Chapin said that what we need is clean, fresh milk rather than Pasteurized milk. This can be obtained if the medical profession will give its attention to the subject and educate the dairymen and the public up to the idea of what constitutes good milk. The addition of cereals to milk often assists its digestion and, if the amylaceous material be dextrinized, there can be no objection to it.

Dr. Carr said that if the milk is fresh and clean, very little heat is needed in its preparation as food for the infant. One must adjust the food to the particular case. At times mother's milk disagrees with the child or leads to rickets, and then even this natural food needs modification.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON SURGERY.

Stated Meeting, Held Monday, October 8, 1900.

Charles N. Dowd, M.D., Chairman.

Strangulation by Meckel's Diverticulum.—Dr. J. F. Erdmann presented two cases of this lesion which have occurred in his private practice in the last few months. About six months ago he

presented a third case of this condition. All three of the cases were successfully operated on. The symptoms in all the patients were strikingly similar to those of appendicitis. When the incision was made there was never full assurance that there might not be found some pathological conditions in the appendiceal region. The treatment of the condition was similar to the excision of the appendix. When the diverticulum was of small diameter it was inverted into the gut. When the diverticulum was of large size it was sewed up precisely as would have been done with a bit of intestine. No untoward event has occurred since operation in any of the cases.

Acute Appendicitis.—Dr. Alexander B. Johnson reported forty cases of appendicitis operated upon during the last few months. Among them were eight cases of generalized purulent peritonitis, three of which proved fatal. In six of the cases no appendix was found. The features that seem to be most conducive to successful operations for appendicitis in Dr. Johnson's opinion are the abundant use of salt solution, the employment of a small incision and the exercise of extreme care in exposing the intestines to the outer air. There must positively be no evisceration, if the patient is to be given the best chances for recovery.

Where the general peritoneal cavity has become infected the use of an abundance of hot sterile salt solution at a temperature of 116° to 118° F. seems to be the best therapeutic measure. The salt solution should be introduced in a good-sized stream from a reservoir at least four feet above the patient's head. The flushing out of the peritoneum should be continued until the salt solution returns perfectly clear. The intestines should not be allowed to project out of the abdominal cavity at any time and fibrinous placques of lymph on the intestines should not be removed.

Danger of Evisceration.—Dr. Johnson considers that the immediate effect of allowing the intestines to project out of the abdominal cavity for any length of time is a practically complete paresis, which very seriously affects all the intestinal functions. This is not due to the septic material in the abdominal cavity, but to the reflex action of the chilling on the delicate nervous mechanism of the intestinal circulation. After trauma with intestinal exposure, even before sepsis has begun its work, it is no unusual thing to see such a paralysis supervene.

Points of Technic.—Where a frankly purulent condition exists, no special effort should be made to avoid opening the peritoneum. Where there is an abscess, however, the intestines should be protected as far as possible from contact with the pus by means of warm pads. As a rule all adhesions should be broken up in order to get at the appendix except where the bands are very dense.

Unusual Complications.—The first case, a boy of sixteen, operated on for purulent appendicitis, had a perfectly normal recovery until the tenth day, when his temperature went up and his pulse showed signs of some infective process at work. On the fourteenth day a large abscess was found to exist between the liver and the diaphragm. This was evacuated and recovery took place. In a second case a man of thiry had had several severe attacks of appendicitis during the last ten years. A moderate-sized appendix was found opening into an abscess. The abscess itself had made a second opening into the intestines and had evacuated itself at intervals. The appendix was cut off and the intestinal opening sutured. Ten days later symptoms of intestinal occlusion declared themselves and bands of adhesion were formed, which had evidently been formed during the old attack of appendicitis. These were cut and recovery took place without further injury. The third case was a colored boy of eighteen who presented no tumor and but slight fever, with considerable pain and marked tenderness. A small abscess was evacuated. Three days later the patient began to have chills. Malarial organisms could not be found in the blood. Careful examination showed that there was some consolidation of the right lower lobe. There was evidently suppuration in the upper part of the abdomen. Signs of an abscess were found in the neighborhood of the liver just below the floating ribs. Incision disclosed quantities of broken-down lymphatics, lying near the hepatic flexure of the colon in front of the right kidney. Pyemia supervened and death took place in ten days. No post-mortem could be obtained.

Drainage.—Wherever suppuration has taken place Dr. Johnson thinks that a glass drainage-tube should be inserted and retained for forty-eight hours. One peculiar post-operative complication came as the result of the use of glass tubes. An enormously stout man was operated on for an appendiceal abscess and a glass tube was inserted into his pelvis and allowed to remain. In all nine inches of tubing were used. Some hours after the operation the patient became delirious and restless and while turning over the tube was broken off. A portion of the broken end seems to have cut an artery for symptoms of shock from internal hemorrhage began to manifest themselves. It proved a very difficult matter to get the broken tube out. It was only accomplished finally by passing a tube of larger size over the broken tube within the abdomen.

Drying of the Intestines.—Dr. John A. Wyeth said that he thoroughly approves of Dr. Johnson's objections to evisceration. Exposure of the intestines to the cool outer air produces not only paralysis of the intestines, but shock. There should be less routine handling of the intestines during an abdominal operation than is the custom at present. With regard to purulent peritonitis, if it is of the extremely offensive variety, Dr. Wyeth considers that irrigation with hot salt solution gives the best hope. A good force of water up to eight or ten feet above the patient should be employed and the water should come

away clear before the flushing is stopped. It is very important after this to thoroughly dry out the peritoneal cavity. No trace of moisture should be left. Along and behind the ascending colon there may remain traces of septic material that the flushing has not taken out and these parts should be wiped thoroughly. For drainage Dr. Wyeth prefers a wick of gauze to a glass tube. A valuable point in septic peritonitis in women is to drain through Douglas' pouch.

Peritonitic Virulence.—Dr. Fessenden Otis said that the virulence of peritonitis differs very much in different cases. In a recent case he saw pus covering the whole of the peritoneum and a fatal ending seemed inevitable, yet practically no septic symptoms developed and the patient recovered. In appendiceal abscesses without odor there may be question of a broken-down gumma. This is important because specific treatment will do much to relieve after effects. In retroperitoneal abscesses in women it is well to bear in mind that they may be opened very satisfactorily through the vagina.

Normal Salines vs. Drying.—Dr. Wiener said that the question of saline irrigation or of dry sponging when purulent peritonitis exists is very important. Both methods have been tried at Mt. Sinai Hospital with excellent results. Every one admits that it is important to dry thoroughly. The question is, shall we irrigate beforehand? There are those who say that irrigation is unnecessary.

Prognosis.—The prognosis of a case with purulent peritonitis is not to be judged from the external appearances of the peritoneum, nor from the amount of pus, nor from its odor. The worst looking cases of peritonitis, in which there is a very fecal odor, are due to the bacillus coli communis, yet these cases have nearly always the best prognosis. The next best prognosis exists in cases due to staphylococci. Streptococci cases give the worst prognosis. A very mild looking peritonitis due to streptococci may prove rapidly fatal. Subphrenic abscess is always peritonitic in origin. The infection runs up along the lymphatics of the colon, but does not necessarily occur on the right side. Such abscesses to the left of the median line are not rare. In a recent case a perinephritic abscess from this cause occurred on the left.

Intravenous Salines.—Dr. Morris said that intravenous injection of physiological salt solution is of distinct benefit after purulent peritonitis. It raises blood pressure, dilutes toxins that are present in the circulation and causes their more rapid elimination. The intravenous injection may be repeated the next day if the symptoms continue severe. The most odoriferous cases of peritonitis are due to the colon bacillus. This micro-organism causes the formation of mercaptan, which has a vile odor. These stinking cases, however, have not as bad a prognosis as those due to the streptococcus, which may have very little odor. In general the odor enables us to distinguish between colon and streptococcus peritonitis. The color of the purulent exudate may be of some help in distinguishing staphylococcic peritonitis. One may with Clark trust to the peritoneum for its own drainage if we aid Nature by the presence of hygroscopic salts in the lumen of the bowel. With reference to drainage by means of gauze it must be remembered than even a healthy man does not stand gauze in his peritoneum well and that we must not subject weak men to its irritating presence any more than is absolutely necessary.

Cleansing Technic.—Dr. Johnson in closing the discussion said that patients who are submitted to abdominal operations should be subjected to as little violence as possible. The more irritated the peritoneum, the readier is the septic reaction and the more paresis and shock result. Cleansing of the intestines and of the peritoneal cavity is of extreme importance, but it must be done by gentle sopping and not by rubbing of the intestines. Drainage through the vagina is important. Vaginal drainage has given such excellent results to one good operator that he suggests rectal drainage for men whenever possible. It seems clear that the individual's resistance to infection is a much more important element in the prognosis of a case than the special variety of microbe that may be at work. Alcoholic and nephritic cases do very poorly. The very stout do not do well and besides there are mechanical difficulties in the way of drainage. The very lean are apt to be of low resistive vitality.

Abdominal Section.—Dr. Howard Collins said that as far as possible the incision for abdominal section should leave the abdominal wall intact for its functions. For this it is especially important not to interfere with the nerve-supply of the muscles that make up the abdominal wall. These nerves emerge from below the ribs, and traverse the tissues of the abdominal wall on the way to supply the different muscles. The lowest nerve emerges from the tip of the last rib and runs along a direct line, the prolongation of which would touch the spine of the pubis on the opposite side. The eleventh nerve comes from the eleventh rib and runs along a line that if prolonged would reach the middle of Poupart's ligament also on the opposite side. The tenth nerve emerges about one inch above the eleventh rib and runs in the same way toward the opposite iliac spine. The course of the ninth nerve is not so definite, but it is situated so high up in the abdominal wall that it is not as liable to be injured as are the others. It is important not to destroy more than one nerve-trunk. If muscles are split instead of being cut, nerves are usually not sectioned. When incisions are made high in the abdominal wall, as for gall-bladder operations, it is not so easy to avoid cutting these nerves, but the intra-abdominal pressure is much less in the upper abdomen and hernia is not liable to occur.

Clavicular Crutch.—Dr. Carter S. Cole of New York presented a splint for fractures of the clavicle. A pad for counter pressure fits over the

scapula behind and the pressure on the clavicle itself can be very well directed. While wearing the splint the patient's arm may be allowed to swing freely at the side. Dr. Cole has used this splint in a number of cases now in hospital practice and it has given very good satisfaction.

Large Intestinal Excision.—Dr. Manley presented a specimen of twenty-nine inches of gangrenous intestine which had been removed from a man suffering from strangulated hernia. The patient, a man of thirty, recovered and, though the operation was done four years ago, symptoms that point to any disturbance of intestinal function have not arisen. For excision of the intestines, Dr. Manley prefers a sloping section because this allows of much better circulation than if the section is made at right angles to the lumen of the intestine. When lateral anastomosis is indicated the opening should not be made in the raphe of the intestine, which is poorly supplied with blood, but midway between the raphe and the mesentery. Better than buttons and plates and bobbins for intestinal anastomosis is some form of suture—the Connell method preferably.

BOOK REVIEWS.

A Manual of Personal Hygiene. Edited by Walter L. Pyle, A.M., M.D., Assistant Surgeon to Wills' Eye Hospital, and having as contributors such well-known specialists as J. W. Courtney, M.D., G. H. Fox, M.D., E. Fletcher Ingals, M.D., Walter L. Pyle, M.D., B. A. Randall, M. D., G. M. Stewart, M. D. (Edin.), and Charles G. Stockton, M.D. 8vo., pp. 344. Illustrated. Philadelphia: W. B. Saunders & Co., 1900.

A physician's success in the treatment of a patient is oftentimes largely due to the attention which is shown to the personal comforts and hygiene of the sufferer. It is difficult to appreciate how much importance is usually attached to a physician's advice relative to the proper method of caring for the various organs and parts of the body in health and disease. A suitable answer to such questions, though always expected of the general practitioner, often necessitates considerable specialized knowledge. The above book has been interestingly written by a number of eminent specialists, but technical phraseology has been avoided, as far as possible, in order that the manual may be of value to all those who are desirous of "an exposition of proper living upon a physiological basis." The chapters upon eating, drinking, breathing, exercise, etc., are full of most valuable suggestions, and a careful perusal of this work would afford many a sufficient knowledge of prophylaxis to obviate the necessity of frequently summoning the family physician in those really unimportant cases which absorb so much of his energy and patience.

BOOKS RECEIVED.

Medical Diseases of Infancy and Childhood. By Dr. Dawson Williams. Second Edition Revised by Dr. F. P. Churchill. 8vo., 538 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York. $3.50.

Die Rolle der Schilddruese bei Stillstand und Hemmung des Wachstums und der Entwicklung und der chronische gutartige Hypothyreoidismus. Von Dr. E. Hertoghe. Deutsch von Dr. J. H. Spiegelberg. 8vo., 69 pages. Illustrated. J. F. Lehmann, Munich. 2 marks.

Die Begutachtung der Erwerbsfaehigkeit nach Unfallverletzungen des Sehorgans. Von Dr. E. Ammann. 8vo., 80 pages. J. F. Lehmann, Munich. 2 marks.

Pathology and Morbid Anatomy. By Dr. T. Henry Green. Ninth American Edition by Dr. W. Martin. 8vo., 584 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York. $3.25.

Laboratory Directions for Beginners of Bacteriology. By Dr. Veranus A. Moore. Second Edition. Demi 8vo., 140 pages. Illustrated. Ginn & Company, Boston. $1.05.

Forty-Fifth Annual Report Upon the Births, Marriages and Deaths in City of Providence, 1899. Dr. Charles V. Chapin, City Registrar.

Die Entwickelung der Biologie im 19 Jahrhundert. Dr. Oscar Hertwig. 8vo., 32 pages. Gustav Fischer, Jena. One mark.

Die Entwickelung der inneren Medizin mit Hygiene und Bakteriologie im 19 Jahrhundert. Dr. B. Naunyn. 8vo., 21 pages. Gustav Fischer, Jena. One mark.

Practical Gynecology. A Comprehensive Text-Book for Students and Physicians. By Dr. E. E. Montgomery. 8vo., 819 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia. $5.00.

Notes on the Mosquitoes of the United States. By L. O. Howard, Ph.D. 8vo., 70 pages. Illustrated. Washington, D. C.

A Book of Detachable Diet Lists. By Dr. J. B. Thomas. Second Edition. W. B. Saunders & Company, Philadelphia. $1.25.

A Text-Book of the Diseases of Women. By Dr. H. J. Garrigues. Third Edition. Revised. 8vo., 756 pages. Illustrated. W. B. Saunders & Company, Philadelphia. $4.50.

A Manual of Syphilis and the Venereal Diseases. By Dr. James N. Hyde and F. H. Montgomery. Second Edition. Revised and Enlarged. 8vo., 594 pages. Illustrated. W. B. Saunders & Company. Philadelphia. $4.00.

Rhinology, Laryngology and Otology and Their Significance in General Medicine. By Dr. E. P. Friedrich. Translated by Dr. F. H. Curtis. 8vo., 348 pages. Illustrated. W. B. Saunders & Company, Philadelphia and London. $2.50.

A Text-Book Upon the Pathogenic Bacteria for Students of Medicine and Physicians. By Dr. J. McFarland. Third Edition, Revised and Enlarged. 8vo., 621 pages. Illustrated. W. B. Saunders & Company, Philadelphia. $3.25.

Bacteriology and Surgical Technique for Nurses. By Emily M. A. Stoney. Demi 8vo., 190 pages. Illustrated. W. B. Saunders & Company, Philadelphia. $1.25.

Practical Manual of Diseases of Women and Uterine Therapeutics. By Dr. H. Macnaughton-Jones. Eighth Edition. 8vo., 947 pages. Illustrated. William Wood & Company, New York.

ORIGINAL ARTICLES.

TREATMENT OF PUERPERAL ECLAMPSIA.

BY J. B. KILLEBREW, M.D.,
OF MOBILE, ALA.

THE causes of puerperal eclampsia are usually divided into the predisposing, the essential and the exciting. From a scientific point of view the study of all these is of interest, but from a practical standpoint the greatest interest is centered in the essential cause, because it is by preventing or removing this that the physician is able to prevent or cure the disease.

Numerous theories as to this essential cause of puerperal eclampsia have been advanced from time to time, practically all of which have now given way to that of toxemia. Just what this toxic agent is or where and how it is manufactured; whether it is produced by the normal processes of metabolism or is due to some condition existing only during pregnancy; or whether it is of bacterial origin has never been satisfactorily demonstrated. The general characteristics of the disease resemble so closely those of other diseases known to be produced by a condition of toxemia that this theory must be accepted until a better one is brought forward.

There seems to be some difference of opinion as to the part played by nephritis in the etiology of this disease, whether it is a cause of the disorder or only an effect. Undoubtedly it may be either or both. At all times, in health and in disease, there is produced in the organism, by the normal processes of metabolism, a certain amount of toxins. These toxins are eliminated by the excretory organs. So long as these organs are capable of eliminating the poisons as rapidly as they are manufactured there is no accumulation, hence no symptoms of toxemia. But just so soon as the amount generated becomes too great for the organs to eliminate accumulation takes place and symptoms of toxemia appear.

The kidneys are the most important excretory organs of the body. When they are diseased their capacity for work is diminished. Under ordinary conditions of life they may still be able, with the help of the other excretory organs, to eliminate all toxins from the system. But when pregnancy occurs the amount of toxins produced is increased. This increase may be so great that the united efforts of the excretory organs, with the most important of them—the kidneys—in a crippled condition, are incapable of eliminating them as rapidly as generated; as a result accumulation takes place and symptoms of toxemia occur. Even perfectly healthy organs are capable of doing only a certain amount. There is a limit to their capacity for work and when the amount of toxins produced is too great for them to eliminate there will be an accumulation and toxemia will supervene. Naturally a patient with nephritis is more liable to eclampsia than one with healthy organs; but there is no reason why a patient with healthy kidneys may not have eclampsia and no reason why one with diseased kidneys may not escape it. At the beginning of pregnancy a woman may have perfectly healthy kidneys; but, by reason of the increased amount of work thrown upon them to eliminate the increased amount of toxins produced and the long continued constant irritation produced in them by the egress of the toxins, they are liable to become inflamed and nephritis results. For the same reason an already existing nephritis may become aggravated. It seems clear, then, that nephritis may be either a cause or an effect of toxemia, or both, first being an effect and then a cause. It is no doubt a predisposing cause of eclampsia, but it is not an essential cause. In most cases of eclampsia the accumulation of the toxins is gradual, as is evidenced by the fact that the onset of the symptoms is gradual. There are usually pronounced precursory symptoms before the occurrence of convulsions. In some cases the toxemia is never great enough to produce convulsions, but only those symptoms indicative of a mild degree of poisoning. In some cases, the great minority, the accumulation seems to be rapid. The onset is then quite sudden and frequently without any of the precursory symptoms, the convulsions being the first symptoms observed.

As the phenomena characteristic of eclampsia are due to an excess of toxins in the system, which toxins are produced in the body, the most rational method of treatment would seem to be to arrest the formation of these bodies. But as it is not known what they are, where or how they are formed, our efforts along this line cannot be successful until such information is obtained. As these poisons are undoubtedly eliminated by the excretory organs the best practical treatment is that which will dilute the toxins circulating in the blood as much as possible and at the same time increase the activity of the excretory organs. The best agent for accomplishing this is normal salt solution. The method of employing it will depend upon the severity of the symptoms present.

A pregnant woman should be constantly under the observation of her attending physician especially after the sixth month. The urine should be examined frequently for albumin. If it is

found the utmost vigilance should be observed. She should be instructed to report at once the appearance of any of the premonitory symptoms of eclampsia, such as violent or continuous headache; any disturbance of vision, especially "flashes of light," dizziness, epigastric pain nausea and vomiting, marked mental irritability or muscular tremors. If any or all of these phenomena make their appearance, whether the urine contains albumin or not, it is a strong indication that toxemia is present and that convulsions are impending; therefore preventive treatment should be begun at once. The patient should live a quiet life, taking a moderate amount of exercise, but never enough to cause fatigue. All excitement should be avoided. The diet should consist of liquids, of which milk should form the principal part. Albuminous foods should be largely restricted. Large quantities of water should be drunk. The bowels should be kept open by the administration of a mild laxative. *Do not purge.* One large, loose movement each day is sufficient. The skin should be kept active by a daily warm bath, after which the patient should be wrapped in a blanket and put to bed where she should remain for an hour or two. If the pulse is hard and tense it may be softened by the administration of nitroglycerin. It also causes an increase in the amount of urine secreted.

While these measures are of undoubted value, they are secondary in importance to the use of normal salt solution, which as a prophylactic agent should be given as high enemata in quantities varying from 1 to 3 pints once or twice in every twenty-four hours. The quantity given should be just as much as the patient can retain. These enemata are absorbed by the mucous membrane of the colon, enter the circulation, dilute the blood, diluting the toxins contained therein. They also stimulate the kidneys and skin to greater activity, thereby causing an increase in the elimination of the toxins. By a conscientious employment of these measures many patients showing evidence of approaching convulsions can be successfully carried through gestation to full term and delivered of a living child without the appearance of convulsions.

If, in spite of these prophylactic measures, the symptoms grow progressively more severe and convulsions occur, or if the patient is having convulsions when first seen, more active measures must be taken. The convulsions should be controlled with inhalations of chloroform. One of the superficial veins at the elbow should be exposed and opened. The dark toxin-laden blood must be allowed to flow from the distal end of the divided vein while normal salt solution at the temperature of about 100° F. is injected into the proximal end. The amount of blood withdrawn will vary with each individual, as will also the amount of normal salt solution injected. Ordinarily from 12 to 24 ounces of blood should be withdrawn and from two to three times that amount of salt solution injected.

The question will arise as to whether bleeding should be practised in all cases. I would say that all patients except those who are extremely anemic should be bled. The withdrawal of a portion of the blood from almost any of these patients will act beneficially if some other circulating fluid is introduced to remedy the loss. Unless this fluid is introduced to take the place of the blood withdrawn, undoubtedly it would be better to bleed only those patients who are very plethoric. In the very anemic it is better to introduce the normal salt solution without bleeding. The withdrawal of blood from these patients certainly removes some of the toxins from the system and makes room in the blood-vessels for the salt solution that is to be introduced. This salt solution dilutes the remaining blood and consequently the toxins contained therein. It acts as a circulating medium and stimulates the excretory organs.

In most of the cases of eclampsia that have been treated by the use of normal salt solution it has been administered either by hypodermoclysis or by enteroclysis. The latter method is entirely too slow to be depended on after the convulsions have begun. Intravenous injection is preferable to hypodermoclysis, because it is more certain and more rapid and is not more dangerous. If the patient is edematous and the circulation sluggish, the salt solution introduced beneath the skin will probably never be taken up by the lymphatics. There is practically no danger in introducing the solution directly into the vein and the results are certain and rapid.

The uterus should be emptied immediately. If the cervix is not fully dilated or nearly so, it must be manually dilated if possible. If this is impossible on account of rigidity, recourse must be had to incisions as advised by Dührsen, which is not now the formidable operation it was before the technic of vaginal work was perfected.

The order in which these means should be employed is as they have been given: (1) Control convulsions with chloroform; (2) bleed the patient and give intravenous injection of normal salt solution; (3) empty the uterus.

Perhaps most operators empty the uterus before giving the infusion of normal salt solution. It frequently requires as much as two hours or even more to empty the uterus, while the infusion or normal salt solution can be given in a few minutes. In some cases the toxemia is so profound when the patient is seen that she will be dead by the time the uterus can be emptied. In these cases there is an almost complete absence of activity on the part of the excretory organs. It seems to me that it is better to give the intravenous infusion of salt solution first and allow it to be doing its work while the uterus is being emptied. I saw a patient a few months ago who died within four hours after the first convulsion. The physician in charge reached her two hours after they began. He first emptied the uterus. When this was accomplished life was almost extinct. Preparations were made at once to give

an infusion of salt solution, but the patient died before the vein could be found.

I recall another instance where the patient had seventeen convulsions during a few hours. The surgeon in charge at once gave an intravenous infusion of normal salt solution. No other treatment was given. The patient did not have another convulsion and was perfectly conscious in a few hours. The uterus was emptied the next day. If the physician in charge of the first patient had given the infusion before he emptied the uterus the result might have been different. If there are enough assistants at hand both operations can go on at the same time with great advantage to the patient's condition.

After these measures have been taken the colon should be thoroughly irrigated. If the convulsions recur and are mild they should be controlled with chloral given in an enema. Should they again become severe another infusion of normal salt solution should be given. This will rarely be necessary. During convalescence the patient should be confined to bed and the bowels and other excretory organs kept active. The diet should be restricted to liquids for a week and then gradually increased as the physician thinks best. A high saline enema should be given twice daily. All excitement, worry and depressing influences are to be avoided. Callers should not be allowed and the nurse should make special efforts to keep the patient in a buoyant frame of mind.

Veratrum viride and chloral have given good results in the practice of many physicians. I have not had any experience with the former. The latter will control the convulsions in many cases, but it does so more by diminishing the excitability of the nerve centers than by removing the causes of the convulsions, although it probably causes some increase in the secretion of urine. Practically the same may be said of veratrum viride. Pilocarpin is dangerous because of the marked depression on the heart and its use is never justified in this disease. Morphine undoubtedly has some temporary effect upon the convulsions, but it should never be used. Like chloral, it unquestionably has a quieting action on the nerve centers, but its effects on the various secretions are important and not to be underestimated. Instead of assisting in the removal of the causes of the convulsions, it retards it by paralyzing all the excretory organs with the possible exception of the skin.

That all methods of treatment heretofore applied in this disease have been unsatisfactory is evinced by the fact that the mortality has been about 25 per cent. Certainly this is sufficient evidence to show that there is room for improvement. Statistics based on the method of treatment given in this article are not large enough to form a very correct idea as to its efficiency, but it is a rational, common-sense method of procedure and offers a hope of better results in the future, especially when improvements in technic have been thoroughly worked out.

OBSERVATIONS UPON THE QUARTAN MALARIAL PARASITE AND UPON THE STAINING REACTIONS OF THE TERTIAN, QUARTAN AND ESTIVO-AUTUMNAL PARASITES.

By CHARLES F. CRAIG, M.D.,

OF SAN FRANCISCO, CAL.;

ACTING ASSISTANT SURGEON, U. S. A.; PATHOLOGIST AND BACTERIOLOGIST TO THE U. S. A. GENERAL HOSPITAL, PRESIDIO OF SAN FRANCISCO.

The occurrence of several cases of quartan malarial fever at the United States General Hospital at San Francisco in soldiers returning from the Philippines has given the author an opportunity of studying with care this comparatively rare organism, and the facts observed are embodied in this paper.

Quartan malaria is the most rare form of malarial infection. Of nearly two thousand cases of malaria, the records of which have been preserved and in which the malarial parasites were present in the blood, only twelve quartan infections were noted. On account of its rarity the quartan parasite merits a careful study, and the fact that it can be easily recognized should be insisted upon, as such recognition will often clear up an obscure case of fever and lead to more correct statistics as to the occurrence of the disease.

The quartan malarial parasite is as distinctive in its morphology as is the tertian or estivo-autumnal parasite. Its cycle of development, as is well known, occupies seventy-two hours. The first form of the organism seen in the blood is a small hyaline disc, very minute and actively ameboid. Although these bodies are generally believed to be indistinguishable from similar tertian parasites, I believe that the quartan hyaline body is more sharply cut and refractive than the tertian, while the invaded corpuscle is of a more greenish hue. In a few hours these small hyaline organisms have grown larger, are less actively ameboid and a few granules of dark brown pigment may be seen within them, generally at the border of the organism. The shape of the organism is either round or triangular, the ameboid motion being very sluggish. The pigment is motionless. I have never seen a pigmented organism which was actively ameboid. The organism is sharply outlined and refractive, while the invaded corpuscle is greenish in color and not swollen. Even at the early stage I believe it is possible to distinguish this form from the tertian parasite, which is dim of outline, of irregular bizarre shape, with active pigment and inhabiting a pale, swollen corpuscle.

In twenty-four hours the distinguishing features of the quartan parasites are fully developed. The organism is sharply cut and looks often as though it were stamped into the blood corpuscle; it is refractive, and its protoplasm often presents a peculiar, finely granular appearance; the pigment is dark brown in color, in the form of rather coarse granules and is generally collected around the edge of the organ-

ism, sometimes forming an almost complete wreath around it; the pigment is absolutely motionless. The shape of the organism at this stage of development is usually triangular, ovoid or round, and it is not ameboid. The invaded corpuscle is smaller than the healthy ones and is of a darker green color. All these characteristics clearly distinguish the quartan from the tertian parasite, which is less sharply cut, and refractive, is more or less ameboid, very irregular in outline, possessing lighter brown, more finely granular pigment, which is always motile, while the infected corpuscle is pale and often greatly swollen.

At the end of thirty-six hours all the phenomena noted are more pronounced, the organism filling about two-thirds of the corpuscle, which seems to be retracting about it; the pigment is increased in amount, but is motionless and collected in rough masses at the border of

1, Normal red blood corpuscle; 2 and 3, hyaline quartan parasites; 4 to 12, various stages in the growth of the pigmented quartan parasite; 13, full-grown quartan parasite; 14, 15 and 16, presegmenting forms of the quartan parasite; 17, segmenting quartan parasite inside red corpuscle; 18, segmenting quartan parasite, the so-called "marguerite form"; 19, segmenting quartan parasite; 20, flagellate quartan parasite; 21, large extracellular quartan parasite; 22, fragmenting quartan parasite; 23, vacuolated quartan parasite.

the organism which is not ameboid. The growth of the organism from this time on is very slow, and it is not until a few hours before segmentation that the full-grown bodies are observed. Such an organism is circular in shape, bordered by a thin greenish layer representing the remains of the infected corpuscle; with numerous clumps of dark brown motionless pigment, not now entirely confined to the periphery of the organism, but scattered through it, the protoplasm of the organism being finely granular in appearance. In many instances segmentation was seen to take place even before the corpuscle was entirely destroyed, the pigment collecting toward the center of the organism and six or more segments appearing within the corpuscle. Most commonly, however, the pigment, in the full-grown parasites collects at the center in a solid, almost black mass, and about the same time all trace of the infected corpuscle disappears, the organism being apparently extracellular. In a short time radial striations are observed shooting out from the central pigment, and these, joining at their extremities, form from six to fourteen oval segments; as a rule, the number of segments does not exceed ten. They are arranged regularly, at first, around the central pigment, the so-called "marguerite forms," but soon they begin to separate and disappear, the pigment at the same time disintegrating and becoming diffused. The number and the beautifully regular arrangement of the segments would alone serve to distinguish this stage of the quartan from the corresponding tertian parasite, but the quartan segments are also more oval in shape, more refractile and somewhat larger. The star-like arrangement of the pigment between the segments, which Thayer considers so characteristic, is generally observed, but I have seen exactly the same arrangement of pigment in tertian segmenting forms; it is probably simply an accidental occurrence, doubtless more common in the quartan parasite, but not at all peculiar to it.

Differentiation from the Tertian Malarial Parasite.—The pigment in the quartan organism is only motile in the very young forms, is always dark brown in color and occurs in round granules or in irregular masses of such granules. It generally occupies the periphery of the organism and tends to become collected at one portion, but in the full-grown parasites the granules and blocks of pigment are scattered throughout the protoplasm.

The outline of the quartan parasite, especially after the first twenty-four hours, is always very sharply cut and appears as though stamped into the corpuscle; the shape of the organism is either round, oval or triangular, and only in the very early hours of its development does it send out ameboid processes of any size; later the ameboid movement consists of a gentle sluggish undulation of the periphery of the organism and even this ceases after the first thirty-six hours.

The protoplasm is refractive and often, on close inspection with a good light and high power, the peculiar, finely granular appearance which has been mentioned is noted. This, together with the sharply cut outline and blocks of pigment, brings to mind very forcibly the similar appearance of the ovoid bodies and crescents of the estivo-autumnal parasite. Indeed, the organism during every stage of its development resembles much more closely the tertian estivo-autumnal parasite as it occurs in splenic blood than it does the ordinary tertian organism. The corpuscles which are invaded by the quartan parasite are invariably somewhat shrunken and greener in color than the healthy corpuscles, but are not often crenated.

From this résumé of the characteristic features of the quartan parasite as it has been observed here, it will be seen that it can easily be distinguished from the ordinary tertian parasite by its cycle of development covering about seventy-two hours, by its smaller size, sharply

cut, more regular outline, refractive, finely granular protoplasm, motionless, darker brown pigment, collected peripherally, lack of or very sluggish ameboid motion, small number of segments which are more refractive and oval in outline.

Staining Reactions of the Tertian, Quartan, and Estivo-Autumnal Malarial Parasites.—The following observations upon the staining reactions of the malarial parasites are the results of study of hundreds of stained specimens, and the methods advocated may be depended upon when stained specimens of blood are desired.

There are many ways of staining the parasites of malarial fever, but a description of a few of the most useful is all that will be attempted at this time. The blood-smears are prepared by carefully cleaning the lobe of the ear, puncturing it with a sterile needle or lancet, touching a clean cover-glass to the resulting drop of blood, and placing another cover-glass over it: the two are then slid very gently and carefully apart and the smear allowed to dry. Care should be taken not to get too much blood upon the first cover-glass and to use no pressure in sliding the glasses apart. After drying, the smears are allowed to harden in equal parts of alcohol and ether for half an hour, when they are ready to stain. The plasmodia are stained by nearly all basic aniline dyes, but not by the acid dyes. For staining I use either Romanowsky's or Chenzinsky's method, preferably the latter. Romanowsky's method is as follows: Two solutions are used—No. 1, a saturated aqueous solution of methylene blue; No. 2, a one-per-cent. watery solution of eosin.—The methylene-blue solution should be at least one week old. The staining solution is made fresh each time it is used and consists of one part of the filtered methylene-blue solution added to two parts of the eosin solution and thoroughly mixed. The smears are placed face down upon this solution and allowed to stain for from one-half to three hours or more. The best results are obtained after about two and a half hours' staining. By this method the colored corpuscles are stained red by the eosin and the parasites a deep blue by the methylene blue. Romanowsky believed that the nuclear chromatin stained a violet color, but I have never been able to confirm his observations. Although very beautiful stained specimens can be secured by this method, I much prefer the method of Chenzinsky, for the reason that it gives a more natural appearance. By Romanowsky's method, and in fact, by most methods, the coloring is very vivid, especially that of the red corpuscles by eosin, whereas in Chenzinsky's method the red corpuscles are stained more dimly, appearing almost natural in color, while the parasites are stained a fine blue, fully as well as by any other method.

Chenzinsky's method is as follows: A concentrated watery methylene-blue solution, diluted one-half with water, is added to an equal amount of a one-half-per-cent. solution of eosin in sixty-per-cent. alcohol. This solution is bottled and kept and is improved in staining qualities by age. The specimens are stained with this solution for five minutes and then washed in water, dried and mounted in Canada balsam. Much better specimens are obtained by staining for two hours or more, and I have secured very fine ones by leaving the smears in the staining solution over night. There are numerous other methods of staining the malarial parasites, but these are the most satisfactory and useful.

A word as to the use of stained preparations for diagnostic purposes: I am aware that a few authorities use stained preparations almost entirely for diagnosis, but I believe that it is a cumbersome and very unreliable practice. Where it is impossible to keep a specimen of blood fresh enough to look at under the microscope, the use of stained preparations is, of course, necessary; but when it is possible to examine the blood fresh, it is always to be preferred, as it is infinitely more exact and satisfactory. I have seen many cases in which the fresh blood showed numerous ring-forms of the estivo-autumnal parasites, yet in which smears taken at the same time and stained most carefully showed either none or at most a very few dimly colored parasites. There is also the danger of mistaking stained granular matter or debris lying upon the corpuscles for the small estivo-autumnal parasites in the smears, and this mistake can be very easily made by one who is unaccustomed to examining such preparations. The only strictly scientific way of diagnosing the various forms of the malarial parasites is by the microscopical examination of the fresh blood, and after all most specimens of blood will keep in a suitable condition for examination, under ordinary circumstances, for six, eight, or even a greater number of hours, despite the text-book statements to the contrary.

Before considering the staining reactions of the plasmodia a brief note as to the most recent staining method devised by Futcher. It is to be recommended whenever speed is desirable in staining or when the fresh blood cannot be examined and a speedy diagnosis is essential. It is as follows: The smears are hardened in a one-per-cent. solution of formalin in ninety-per-cent. alcohol for from a half to one minute. They are then dried and stained for twenty to thirty seconds in the following solution of thionin, known as Marchand's: Saturated solution of thionin in fifty-per-cent. alcohol, 20; two-per-cent. solution of carbolic acid, 100. The solution should stand several days before using. After staining, the specimen is washed in water, dried, and mounted in Canada balsam. The red corpuscles are stained a very slight greenish hue, while the parasites are deep violet in color. Care should be used not to stain for too long a time, and also not to allow the formalin solution to act long, as it seems to cause a degeneration and vacuoliza-

tion of the red cells. The method stains the estivo-autumnal rings very satisfactorily.

Staining Reactions of the Tertian and Quartan Malarial Parasites.—In properly stained preparations of the tertian and quartan parasites two distinct portions can be made out—a deeply staining ectoplasm and a dimly staining endoplasm. The endoplasm is really the nucleus of the parasite, and sometimes there can be seen, situated eccentrically, between the ecto- and endoplasm, a very deeply stained spot, the nucleolus, and this contains the greater part of the chromatin substance. These appearances are best observed in half-grown parasites which are not undergoing marked ameboid change of form. The ectoplasm contains the pigment. The nucleus is generally round or oval in shape and eccentric in situation. The very youngest tertian and quartan parasite is represented by a blue ring, the center of which is almost colorless. At some portion of the junction of the central colorless area and the blue-stained ring may often be seen a deeply stained dark blue dot. Here we have the clearly differentiated ectoplasm, stained blue, the endoplasm or nucleus, almost unstained, and the deeply stained nucleolus. As the organisms grow, pigment granules appear in the ectoplasm or stained portion, and by reason of the change of shape due to the ameboid motion the central colorless nucleus is not easily made out, it being often situated in one of the pseudopodia. By reason of the ameboid changes in the shape of the parasite and the situation of the pseudopodia at different levels in the infected corpuscle, it often appears as though there were two or more stained parasites within one corpuscle. In the stained ectoplasm both deeply and dimly stained areas can be distinguished. These occur without any regularity and are probably due to different quantities of the stained protoplasmic substance collected at certain places. It will often be noticed that the extremities of the pseudopodia are stained much more deeply than other portions of the parasite. Very seldom is any pigment seen within the clear, almost unstained nucleus. Often, however, young forms are seen which stain almost uniformly throughout, no trace of a nucleus being visible.

As the parasites grow larger and approach full development, the distinction between the ectoplasm and the nucleus is gradually lost and is often represented simply by a more or less irregular, dimly stained area free from pigment. Often, even this appearance is absent and the parasite consists of a pretty uniformly stained pigmented mass of protoplasm. The small, deeply stained spot or nucleus always disappears before the parasite attains its full growth and is by no means constant even in the young forms. Just before segmentation, when the pigment has collected in a clump, the stained tertian or quartan parasite presents a peculiar, dotted or mottled appearance, due to small, very deeply stained dots or spots scattered through the more deeply stained protoplasm of the parasite. As segmentation advances and the parasite begins to split up, it will be seen that these darkly staining dots are in reality the nucleoli of small dimly stained rings or young tertian or quartan parasites and correspond exactly to the young stained forms first described.

The pigment does not stain appreciably in well prepared specimens, and the parasite which shows the centrally situated clear, very dimly staining area or nucleus, is always collected within the stained ectoplasm. This agrees well with the well-known fact that in the fresh specimen the pigment granules are almost always collected at or near the periphery of the organism in its young pigmented stage.

Staining Reactions of the Estivo-Autumnal Malarial Parasites.—The staining reactions are similar for both the quotidian and tertian estivo-autumnal parasites.

The "ring-forms" of the estivo-autumnal parasite show a more or less deeply stained outer position, a round, or oval unstained central position, and a very deeply staining minute dot, situated at some point at the periphery of the stained ring. As the parasites grow, the endoplasm stains faintly, and the distinction between it and the ectoplasm becomes less marked. The deeply staining dot disappears, and just before segmentation the parasites stain a uniform blue throughout. The pigment granules, if present, are collected in the stained outer portion in the half-grown parasites and at or near the center just before segmentation. The individual segments stain as do the intracorpuscular rings, the only difference being that they are smaller.

Staining Reactions of the Crescents and Ovoids.—The crescent form of the estivo-autumnal parasites presents many interesting staining phenomena. In those crescents in which the pigment is collected near the center, the organism as a whole takes a rather dim blue color, the poles staining much more deeply, while the center in which the pigment lies is often unstained or but dimly stained. At each pole, as a rule, may be seen a very deeply stained semilunar portion, extending to its periphery and covering the horns of the crescent. The appearance presented is that which would result had each horn of the crescent been dipped into a darker staining fluid and withdrawn. Between the deeply stained horns of the crescent and lying within the more dimly stained protoplasm are often seen very deeply stained round or oval spots, irregularly distributed. In some crescents these deeply stained spots are very distinct and occupy a large part of the protoplasm of the crescent. As a rule, the area in which the pigment lies and that immediately surrounding it stain very faintly, or not at all, but it is not rare to see a darkly stained belt or band passing through the center of the crescent and seeming to divide it into two parts. This appearance,

however, is not common and does not by any means prove the dual nature of the crescent. Surrounding the crescent, in the majority of instances, is a narrow eosin-stained border, believed to be the remains of the red corpuscle in which the crescent was developed. This red-stained border does not always, however, entirely surround the crescent; sometimes it is observed only between the two horns, forming the so-called bib; sometimes it is absent there and present over the convex portion of the crescent; sometimes it can only be seen covering the horns or one horn of the crescent. It is often observed to be broken or ragged in outline and interrupted in places, thus suggesting the gradual disintegration of the red cell. Crescents are often observed which do not show any eosin-stained border, and in such cases we may assume that the destruction of the red cell is complete and the crescent is free in the blood plasma.

While the above description applies to the majority of stained crescents, many exceptions occur. Quite often, crescents are observed stained almost uniformly throughout; others do not present the deeply stained spots or polar staining; others stain very dimly at one pole and deeply at the other; in fact, it would be almost impossible to describe all the variations which may occur, but in the vast majority of examinations of stained crescents the description given will be found correct. There is no evidence of a nucleus in crescents. The ovoid bodies stain exactly as do the crescents, so far as I have been able to observe, save that the polar staining is not so pronounced.

In closing this article the author wishes to express his thanks to Col. A. C. Girard, the commanding officer of the Hospital, for his interest and enthusiasm in the study of tropical diseases and for the uniform encouragement which he has invariably given him in his work.

IS LIVING ANIMAL TISSUE CAPABLE OF NEUTRALIZING THE EFFECTS OF STRYCHNINE AND VENOM? AN EXPERIMENTAL STUDY.[1]

By S. J. MELTZER, M.D., and G. LANGMANN, M.D., of New York.

In an article entitled "A Contribution to the Knowledge of the Neutralization of Poison" (*Ein Beitrag zur Lehre von der Entgiftung*) Drs. v. Czyhlarz and Donath, of Nothnagel's Clinic in Vienna, have recently published in the *Centralblatt für innere Medizin* (No. 19, 1900) a communication which attracted considerable attention. They have tightly constricted a posterior extremity of guinea-pigs and injected effective doses of strychnine in its distal end, and found that when the ligature was removed after an hour or later, the characteristic effects of strychnine were not produced. The authors interpret their observation by the strained assumption that by the prolonged intimate contact of the tissue with the poison the latter becomes "fixed" or neutralized. They refer also to the use of ligature in cases of snake-poisoning and suggest that the favorable effect of this therapeutic procedure might be due chiefly to the fixing of the venom by the animal tissues.

The fixing or binding of toxins by the cells or fluids of the animal body is now quite a familiar idea, its far-reaching extension to all kinds of vegetable and animal poisons should, however, certainly not be accepted without conclusive proofs.

The statement made in Weir Mitchell's older writings, that a patient died from a snake-bite two hours after removal of the ligature which had been tightly applied for sixteen hours, was the incentive for us to test, at first on venom, the assumption made by v. Czyhlarz and Donath. However, the results which we obtained in these experiments induced us to repeat the experiments of the above-mentioned authors with strychnine. We are going to report here briefly the findings of these experiments with a short discussion of their proper interpretation.

Experiments with Venom.—We have injected the venom of the rattlesnake (*Crotalus horridus*) into one of the posterior extremities of rabbits and guinea-pigs. Death is here the only sure sign of the poisonous effect. All other symptoms are not sufficiently definite to be used in experimental comparisons. We have therefore in our experiments measured the effect of the poison chiefly by the time which elapsed between injection and death. The fatal dose was established every time by a control-experiment, although we knew from former experience that a dose of 0.03 gram of fresh poison generally kills a rabbit in from three to four hours. Guinea-pigs require a dose three to four times as large as that which is fatal for the rabbit.

Our experiments permit the conclusion that temporary ligation of the leg in which, peripheral to the constriction, a fatal dose of venom was injected as a rule retards the fatal outcome by four to ten hours. In some cases life was prolonged for one day and exceptionally even for a few days. The longer the leg remained ligated the longer was death deferred and the more severe were the local reactions, such as hemorrhagic edema, abscesses, gangrene, etc. When the leg was constricted for a few hours and the venom injected soon after removal of the ligature, the fatal outcome was also considerably postponed.

We can say that our experiments with snake-poison indicate in a general way that venom does not become neutralized by animal tissue, but that a ligature retards its resorption into the circulation on account of the impairment of the absorbing capacity of the tissues of the leg caused by the prolonged constriction.

It must, however, be admitted that the general question whether poison becomes neutralized by

[1] From the Pathological Laboratory of the College of Physicians and Surgeons, Columbia University, New York.

living tissue cannot be properly decided by experiments with venom. It could be claimed, in the first place, that in this case the poison is not sufficiently fixed by the tissue, because the latter loses a great deal of its vitality immediately on coming in contact with the venom; a supposition which seems, indeed, to be sustained by the appearance of local inflammatory reactions soon after the injection of this poison. Furthermore, it could even be assumed that the venom does become neutralized, but death results finally not from the venom but from the resorption of toxic products from the greatly disintegrated tissues of the leg; an assumption which seems to hold good for some late deaths occurring after snake-poisoning.

Experiments with Strychnine.—The facts contained in the communication of v. Czyhlarz and Donath regarding the influence of the ligature upon strychnine-poisoning would greatly gain in importance if it would hold good for all or, at least, many animals and when even comparatively large doses of strychnine are employed. The wording of the statement made by these authors seems to imply such an anticipation, although they have apparently experimented only with guinea-pigs, an animal not very sensitive to the effects of strychnine, and have not even stated what doses they employed in their experiments. In our experiments we have employed, in addition to guinea-pigs, rabbits and frogs. The last are very sensitive to strychnine. Smaller doses could be employed on them, thus offering the tissue a still better chance for complete neutralization of an effective dose. Besides, the hind leg of a rabbit is many times the size of that of a guinea-pig and has at its disposal much more tissue and therefore readier means to conquer a poisonous dose of strychnine. In some cases we have also employed massage in order to bring the poison in intimate contact with a wide area of the tissue of the constricted extremity. In all our experiments we employed sulphate of strychnine in one-per-cent. solution.

Experiments on Frogs.—When the dose of strychnine injected into a posterior extremity of these animals amounted to 0.0002 gram the ligature had apparently no influence at all on the poisonous effect. With a dose of only 0.0001 gram the tetanus appeared eight to ten minutes later than in the normal frog used for control, and was also less violent and of shorter duration. Doses smaller than 0.0001 gram had no reliable characteristic effect even in normal unligated frogs. Briefly stated, the results were: The ligature had no influence at all upon doses above the minimum; the effect of a minimum dose of strychnine was retarded a little but never abolished.

Experiments on Rabbits.—In the experiments on these animals the negative results were still more pronounced. Doses of strychnine amounting to 0.001 gram pro kilo rabbit produce in an animal whose leg was previously constricted a tetanus of the same intensity and after the same lapse of time as in a normal animal used for control. Doses less than 0.001 gram pro kilo do not have uniform characteristic results in control-animals either. Even a simple retarding effect of the ligature has not been established.

The experiments on frogs and rabbits have shown pretty conclusively that the tissues of these animals at least do not neutralize any dose of strychnine, or, at least, that such a neutralization is not demonstrated by the method of investigation employed by us in repetition of the experiments of v. Czyhlarz and Donath.

Our experiments, however, cannot be considered as a contradiction to the statements of the above-mentioned authors, inasmuch as they have derived their observations from a study upon guinea-pigs whose tissues perhaps possess the special property of neutralizing strychnine. We might even go so far as to assume that the well-known greater resistance of guinea-pigs to the effects of strychnine might be due just to this special capacity of the tissue of guinea-pigs to fix certain amounts of strychnine. To get more light on this interesting question we have carried out a series of experiments on guinea-pigs, studying the effect of the ligature under different conditions and varying doses of strychnine.

Experiments on Guinea-Pigs.—Doses of 0.001 gram do not produce characteristic effects in animals weighing 250 grams, the average weight of a guinea-pig. A dose of 0.002 gram brings out in a normal animal a characteristic tetanus in a few minutes, but upon such a dose the ligature has no perceptible influence; the tetanus appears with the same intensity and at the same time in a constricted animal as in an animal without previous ligation. However, the effective minimum dose lies between the two mentioned doses; it is 0.0015 gram; and with this dose we have repeatedly established the fact that in an animal whose leg was temporarily constricted, in the great majority of the experiments, the strychnine brought out no characteristic effects, and even in the few exceptions the tetanic outbreak was of a very mild nature; while in the control-animal a similar dose had the characteristic effect. We can thus say that we have confirmed the statement of v. Czyhlarz and Donath as far as the point of fact is concerned, namely, that a ligature is capable of annihilating the effect of strychnine, but with the restricting modification that this statement applies only to guinea-pigs and to minimum effective doses. We may also express the results correctly by saying that the ligature reduces an effective minimum dose to an ineffective subminimum.

But does this mean that in these cases the entire dose of strychnine remains in the leg and none becomes absorbed into the circulation? To throw light on this question we made the following two kinds of experiments. First, in such ligated guinea-pigs in which after removal of the ligature the injection of 0.0015 gram remained without effect, we soon injected into another part of the body 0.001 gram, *i. e.*, a sub-

minimum dose which would otherwise have had no effect, and this injection brought out in a few minutes characteristic convulsions. That means that from the ligated leg enough strychnine was absorbed to increase the newly-injected subminimum to an effective minimum dose. This amounts to an absorption from the leg of at least 0.0005 gram, about one-third of the injected dose.

In a second series both posterior extremities were simultaneously ligated and in each 0.0015 gram of strychnine was injected. In these cases a well-characterized tetanus appeared on removal of both ligatures. In these cases it appears that at least one-half of the injected quantities were absorbed from the legs. Moreover, the mere fact that the ligature does not have any influence upon doses of 0.002 gram seems to demonstrate that of this quantity at least 0.0015 gram becomes absorbed, which amounts to about three-quarters of the injected dose.

The positive result regarding the influence of the ligature is accordingly reduced to the modest fact that in guinea-pigs, which are less sensitive to the effects of strychnine, a ligature reduces the absorption of the injected dose of strychnine by a small fraction, a reduction sufficient to turn an efficient minimum dose into a subminimum. Is it necessary to assume that this small fraction was *fixed* by the tissues of the leg and by this and this alone was prevented from being absorbed into the circulation? And is such an assumption even probable? A leg which was subjected to a long, firm constriction certainly contains as a result many changes which are capable of affecting its power of absorption, whether this latter be accomplished by physical or cellular forces, and whether it takes place by the blood-vessels or by way of the lymphatics. The constriction causes a destruction or at least an impairment of the vitality of some of the tissues; it causes the occlusion by thrombi of many blood-capillaries, and it probably causes in some of the lymph-spaces a conglutination and in others obstruction by lymph-clots, etc. Under these circumstances, is not a diminution in the absorption in the injected doses to be expected, simply as a consequence of the impaired power of absorption within the tissues of the ligated leg? And now if, in addition to the factor of impaired absorption, the tissue would bind some portion of the injected strychnine, would not the portion of strychnine which is not becoming absorbed be considerably larger than that fraction which we find missing in reality?

We have, however, endeavored to clear up this point by an experimental arrangement. If the supposition is correct that animal tissue can neutralize a certain amount of poison, we might expect that the neutralization will be in direct proportion to the amount of tissue and in inverse proportion to the amount of poison which comes into play. We therefore constricted simultaneously three extremities of a guinea-pig and in each of the extremities injected simultaneously an equal amount of strychnine which we varied in different animals. By this arrangement the strychnine comes in contact with a larger amount of tissue than in the original experiment, and we ought to have found that larger doses of strychnine prove to be ineffective. We obtained, however, just an opposite result. Even when only 0.0005 gram was injected in each extremity, the sum total of which for one animal was just 0.0015 gram, a violent tetanus set in on removal of all the three ligatures. A dose of 0.0015 gram injected in one constricted extremity becomes ineffective, the same dose divided among three extremities, *i. e.*, three times as much tissue, proves to be very effective. The conclusion therefore is unavoidable that the tissue does not interfere with the effect of the strychnine. Apparently the success in our last experiment is due to the fact that the number of unimpaired paths of absorption is greater in the three constricted extremities than in one.

Von Czyhlarz and Donath, however, state that they have performed experiments which demonstrate that the absorption within the ligated leg is not impaired. They have kept a leg constricted for a few hours and shortly before removing the bandage have injected strychnine, the animals, they state briefly, succumbed in a few minutes under characteristic convulsions. Such a general statement proves in a general way that absorption can take place even from a ligated leg. This could be satisfactory to the authors who apparently assumed that when the injection was made just before the constriction none of the strychnine became absorbed, which could then be due only to some other factor than impaired absorption. We have shown that by far the greater part of the injected strychnine becomes absorbed even with a prolonged constriction. To prove that the retained small fraction was not due to some degree of impairment of the absorption power in the constricted leg, it would only be necessary to show that the absorption did not suffer at all, *i. e.*, it would require a comparison of the power of absorption from such a leg with that of a normal non-ligated leg; minimum doses would have to be used and the intensity and duration of the convulsions noted, etc. All this the authors have not done, they do not speak of comparison experiments and do not even tell us what doses they employed in these experiments. We may then safely say that they have not proven and not even attempted to prove that by prolonged constriction the power of absorption does not suffer to any small degree which would suffice to turn the absorption of an effective minimum dose into an ineffective subminimum dose. It would be very strange indeed if a constriction lasting from three to four hours, which often enough causes visible changes in the extremity, would not alter in the least the power of absorption of such a limb.

We have, however, again tested this point by direct experiments with the following results: When a leg was kept constricted for from one

and a half to two hours and immediately on removal of the constriction 0.0015 gram, *i. e.*, an effective minimum dose, of strychnine was injected into it, the effect of the strychnine was visibly modified; the convulsions appeared later than usual, did not last long and were altogether of a mild type, distinctly milder than in the control-animal. The strychnine effect was less marked the more distant from the place of constriction the injection was made, especially when it is made toward the distal end. On the other hand, if the injection was made near the place of constriction and in a centripetal direction the effect was sometimes very little different from that observed in a control-animal.

Our results can be briefly summarized as follows: Constriction of an extremity of an animal, even after removal of the constriction, markedly retards the fatal outcome of snake-poisoning and transforms an effective minimum dose of strychnine into an ineffective submiminum dose. This effect is apparently due to some impairment of the power of absorption within the constricted leg. It seems quite certain that no part of either poison becomes fixed or neutralized by the tissues of the animals experimented upon. The claim of v. Czyhlarz and Donath to that effect could not be sustained.

EYE-WORK IN GENERAL PRACTICE.

By S. W. S. TOMS, M.D.,
of Nyack, N. Y.;
Instructor in Diseases of the Eye in the New York Post-Graduate Medical School and Hospital.

In the early years of my professional work I met a class of patients presenting conditions of a nervous type of deranged functions difficult to understand and refractory to treatment. The obscurity of the exciting causes made diagnoses speculative because of the variety of symptoms in different individuals. After seeing a large number of such cases I felt there probably was a latent causation common to the entire class.

The symptom-complex comprised anorexia, nausea and sometimes vomiting; an obstinate neuralgia, generally affecting some of the cranial nerves; vertigo or agarophobia, alternating perhaps with an irregular headache; in others gastrointestinal indigestion, sour stomach or gaseous dyspepsia. These anomalous conditions, purely functional, could not be accounted for by organic disease, and rational measures of therapeutics were utterly futile in giving permanent relief. I failed to find any solution for these departures from the normal standards of health in the medical literature I possessed, or in post-graduate study. Most of these cases were not in those of purely neurotic temperament *per se*. Their complaints were of a fixed character rather than changeable, and their physical conditions were often of the best.

In discussing these unsatisfactory cases with a *confrère*, a most thorough-going and indefatigable investigator, he said he believed that such cases belong to a class whose nervous reserves were being continually exhausted, or, as he expressed it, "nervous force going to waste," because of some defect, not in the supply, but in overuse or leakage. He himself was a sufferer from "nervous dyspepsia." He had studied his own case, because well qualified men had failed to relieve him. Every organ had been examined and most of them treated by specialists, not excepting his eyes. While in New York City he spent some time at the library of the Academy of Medicine where he looked into some articles on heterophoria. He visited me and for the first time had an ophthalmic examination made. This examination revealed a muscular defect, the surgical correction of which brought relief. On that occasion I derived a most useful suggestion, from which I have been able to help many of my patients who otherwise would still be sufferers.

In presenting an article on this subject I am conscious of the suspicion that exists in the profession of any departure from the established ideas of the past. Some there are in the profession who are so conservative that they disbelieve anything that they themselves are unable to practice. Others treat such matters with indifference; while still others have deep dyed-in-the-wool prejudices. It is only necessary to listen to discussions of "new treatments" in medical society meetings when electro-therapeutics, or some similar measures are credited with accomplishing new results, to hear most unreasonable criticisms expressed; generally by opponents whose experience has been the most crude or who have had none at all.

The same is true regarding much that can be accomplished by eye treatment for many symptomatic diseases functional from peripheral irritation. The general practitioner cannot be blamed for holding himself aloof and for not accepting these truths when many of the older specialists in ophthalmology claim there is no such thing as "muscular asthenopia" after proper correction of refractive errors. I believe these specialists belong to one of the classes of conservative practitioners I have just mentioned. They refuse to acquire the technic or to use the instruments which are necessary to demonstrate that there is a condition of muscular imbalance which is as fruitful in producing functional reflex disorders as are refractive errors. It is as reasonable to deny the germ theory of disease because of ignorance of bacterial technic. There can be no question that, if an oculist ignores the investigation for, and correction of, muscular asthenopia, he neglects a most important duty he owes his patients and leaves a percentage—quite a proportion—of his cases unrelieved. This was testified to in a recent personal conversation with one of the surgeons of the Post-Graduate Hospital, who by a series of tenotomies obtained great relief.

I have a case in mind that is full of suggestive neglected possibilities. The patient is a man of twenty-four, now confined in one of the colonies

for epileptic insanity. He never had had a convulsion until he was ten years of age—the period of life when active school-work begins and use of the eyes becomes considerable. There was no family history, even of the remotest, of epilepsy. His mother is a sufferer from headaches. The attacks continued despite vigorous medication as long as he attended school. He was taken away from his studies and the convulsions ceased without medicine for three years. An attempt to take up art, after school-work, caused a relapse, the convulsions became more severe; and continued application to his art, combined with heroic drugging, brought on insanity. What better suggestive idea of the factor of eye-strain as the direct excitant of symptomatic epilepsy could be had than the citation of such a case.

The irritation to the brain from the reflex cause, when continued, eventually produced the true disease. The complicating insanity is perhaps the result of the long-continued use of bromides. The epileptic state has been produced by other reflex irritations, *viz.*, adherent prepuce, nasal deformities, etc., as may be found from abundant examples recorded in medical literature.

The factor which so often obscures diagnosis in these eye cases is that they rarely have any symptoms directly referable to the eyes themselves: on the contrary, many of them have better than normal vision. I am often confronted with the statement, "I am sure, doctor, that my headaches do not come from my eyes, as I can read the names of the steamboats on the river." It is these far-sighted eyes (hyperopic) that so frequently have their concomitant symptoms; and, moreover, a considerable proportion of those having a muscular anomaly are perfectly emmetropic or have normal vision. The efforts that the brain centers make in the acts of accommodation and adjustments in producing perfect pictures on the retina and in binocular single vision, more especially in near work, produce eye-strain, and reflex symptoms develop. When we realize the thousands of intricate and complicated adjustments required in the use of the eyes in properly conveying visual perceptions to the brain, can it be wondered at that nervous symptoms develop if those wonderful organs lack mechanical adjustments to work easily? Yet, as I have intimated, very few direct symptoms from defects are experienced in the eyes themselves: hence, the general practitioner frequently overlooks the indirect cause of nervous phenomena.

Direct eye symptoms are no more frequent in reflex functional derangements than is pain the first symptom of cancer. Another very interesting fact exists in this connection. It is not the high degrees of refractive errors that cause the most trouble, but the moderate and frequently the very low degrees that produce reflex symptoms. In the high degrees the blurring of the images on the retina cannot be overcome by any effort the brain may make through the nervous impulses sent to the adjusting and focusing apparatus of the eye. It is too gross for the ciliary muscles to act, and the brain ceases to send impulses, and the visual center accepts the imperfect impression without tiring. The schoolboy with such a state of affairs is a poor writer and speller and may be "a dunce," but his general health does not suffer. The girl with a slight astigmatism or a latent divergent squint (exophoria) will have headaches, get tired easily, is often sick at her stomach and is always "nervous." She has vision as acute as most normal eyes, but it is at an expense of nervous force. It is not the squinting eye that produces nervous troubles; for often the squinting eye is amblyopic, but, on the contrary, the latent not the manifest squint subjects often have nervous manifestations of some form or other.

Some pathological conditions occurring in later life are of interest because they are more than probably due to the anomalies under discussion. Glaucoma is more frequent in astigmatic eyes; and cataractous eyes are frequently abnormal in refractive errors. This is but one of the potent arguments why all eyes should be properly examined in childhood. A child's entire future may be dependent on the neglect of this; his education, his health, and in after life a helpless blindness might be prevented. Schoolteachers and parents often stigmatize a scholar "a dunce" because he cannot acquire knowledge through defective special sense organs. A child is often taken out of school on the advice of the family physician, for the reason that he or she suffers so much from headaches, "nervousness," etc., because there exists some latent eye defect the correction of which would allow the acquirement of an education and preserve a well balanced nervous system.

Although it is not my intention in this paper to cite pathological cases, but to relate those of functional derangement occurring in my practice, I desire to report a suggestive case of functional disorder due to congenital astigmatism. The patient was a woman of middle life infected with lues by her husband. After the primary lesions both eyes were affected by retinochoroiditis and the right with iritis. She never had worn glasses to correct a defect of 3.50 diopters of hyperopic astigmatism, and it seems to me that the normal standard of nutrition manifested in structure resistance was so perverted and lowered that the disease fastened itself in the weakest tissues, which in this case were the eyes.

To illustrate the ideas already set forth some cases are reported which may interest the general practitioner. A few others have been reported in the December (1889) number of *The Post-Graduate*, entitled "Ocular Reflex Neuroses."

Case I.—Hysteria gravior with delusions. H. B., aged twenty-nine years, German, single, housemaid. Father died of apoplexy. Mother alive and well. There is a neuropathic tendency in the family. Patient has had good health ex-

cept for an attack of measles at seven years of age. At that time her eyes were seriously affected; for weeks she was confined to a dark room and it was six months before she regained her sight. Following this the right eye squinted inward. She had diphtheria at eight, but recovered without sequelæ; also, scarlet fever at sixteen. She has always worked hard at housework and in Germany overtaxed her eyes by sewing at night by a poor lamplight. On December 23, 1898, the patient, having been left alone in care of her sister's children, was suddenly taken while at dinner with a sense of choking as if something had lodged in the left side of her throat. I was hastily summoned and instead of finding her coughing, choking and strangling saw a somewhat excited young woman who told me in a deliberate way that she was choking to death; that while eating plain chicken broth she had (as she supposed) accidentally swallowed a piece of meat or bone which had lodged in her throat, not in the larynx, but up behind the palate on the left side. I saw the chicken broth. It was clear and had no particles of meat in it. She described the sensation as something in her throat (pharynx) and radiating upward into her left ear. I could neither see nor feel anything there, yet she was insistant upon my removing the supposed cause of her trouble. Suspecting hysteria I took her to my office, carefully examined her, but, finding nothing abnormal, determined to create a mental impression by hurting her. I told her I had no instrument suitable for removing it and would use my finger to dislodge it and it probably would go down her throat. I produced considerable gagging with my finger in her throat, withdrew it, directing her to swallow quickly; I then made an application of cocaine and waited. She left my office convinced she had been relieved; but to my surprise early next morning she reappeared, stating that she could not swallow and there must be some chicken still remaining. Almost daily, often several times a day, at all hours, day or night, this poor girl came for an examination to be assured the throat was clear. For seven weeks she refused to eat, taking nothing but strained soup and broths and often would choke trying to swallow these. If she knew I was away from home she positively refused all kinds of liquids. She would suddenly grasp her throat, make frantic gasping and choking manifestations, and on two occasions had a clonic convulsion, greatly alarming her friends. She said she could not get her breath and was dying, as her heart beat so rapidly. She lost about twenty pounds in weight and became weak and unable to leave her bed. Repeated physical examinations were absolutely negative. She had two hyperesthetic spots in her throat on the left side below the tonsil. When these were touched it caused a clonic spasm of the muscles of deglutition and those of her larynx. The examination of her nose and ears was negative, as was that of the thorax, abdomen and pelvic organs. She had no areas of cutaneous anesthesia. The routine treatment for hysteria was but partially successful and no moral influence could induce her to eat. On one occasion I took lunch with her, but she could not swallow any solid food. I was at a loss for further resources, but thought an examination of her eyes the next in order, and on March 1, 1899, I carefully went over her refraction and muscular balance. I found she had compound hyperopic astigmatism of different degrees in each eye, and she disclosed homonymous diplopia at once when a red glass was put over either eye. This manifest evidence of a latent convergent squint, requiring a strong prism to unite the images, seemed a paradox when abduction was measured, it being double that of adduction. The external muscles overcame a prism of 30°, while the normal is but 6° to 8°. The internal muscles measured only in R. E., 14°; L. E., 18°—at least 50 per cent. too weak. This state of affairs called for a mydriatic; the effect of this was most surprising, for the same afternoon a desire for food was experienced and she commenced to take solids that day—the sensation in the throat was no longer the controlling and inhibiting influence over her normal appetite. The first day she got her glasses, the third after the mydriatic she partook of solids seven times. Within a week the last vestige of the throat symptom of hysteria had left her, and her return to health was rapid and satisfactory. She has not had any return of her symptoms since.

I performed two tenotomies on her external muscles, reducing the abduction from 30° to 4° without increasing the power of the internal, at the same time reducing an esophoria of 13° to 2° to 5°. This gave her binocular single vision and freedom from all discomfort. Her vision before treatment was: R. E. 20/200 w. + .75 ⌒ +3.25 ax. 90° = 20/50; in L. E., 20/50 w. + .75 ⌒ + 2.75 ax. 90° = 20/30. Before tenotomies on the external recti muscles she had a sensation of constriction over a small area of the scalp and diplopia, both of which were relieved by the operations. She received no medication whatever after her glasses were procured and the only other treatment she had was a few days of static electricity.

Here was a case with excessive abduction yet having a high degree of esophoria and homonymous diplopia—these last two conditions opposed to excessive abduction. The indication for interference, however, was plain to me despite the apparent esophoria and homonymous diplopia and the tenotomies on both externi reduced the three abnormal conditions and nearly balanced the eyes.

Case II.—Reflex epilepsy depending on a very slight refractive error, the relief with cylinder and spherical glasses, preventing unequal contraction of the ciliary muscles, being sufficient to prevent attacks. A. H. S., aged thirteen years. Neurotic, rheumatic and tuberculous family his-

tory. Had first attack at ten. Frequency, every four or five months. *Petit mal* diurnal. He was treated for dyspepsia with negative results. Patient was referred by his family physician to Dr. Francis Valk of New York, who prescribed glasses and found a slight insufficiency of right internus. He wore glasses constantly and had no further attacks. He lost his spectacles and went without them, and in a few months the attacks recurred. He was subsequently referred to me. I found his vision to be: R. E., 20/20; L. E., 20/20 +; would not accept any glass. Under mydriatic R. E. 20/20 + .50 cyl. ax. 90° = 20/15. L. E., 20/70 + 50 D ⌒ + .50 ax. 90° = 20/15; muscular balance good. These full correction glasses were given. He has had but one attack since, occurring one day while not wearing his glasses. The muscular trouble does not seem to be a factor, as it is but slight, and since his refractive errors are corrected it has played no part in his attacks. It is now over a year since he was fitted and I have recently seen him.

This case is an example of a very slight refractive error, yet the result of correction clearly proved the importance of its recognition under full mydriasis and correction on unequal refraction.

Case III.—Periodical migraine depending upon uncorrected refractive errors of vision. Wm. A., aged twenty-six years; married, American, carpenter; negative family history. Patient gives a history of "sick headaches" since he was a school-boy, occurring every six weeks when he was working. These attacks are accompanied by vomiting, prostration, and at times fainting attacks, facial pallor, small thready pulse of high tension and frequency, lasting from one to three days. The headache is general, of the angiospastic type, numbness of the extremities, "fortification spectrum," etc. This patient had no alcoholic or tobacco habits, has led a regular life, has no specific history, no malaria or rheumatic symptoms; urine negative; bowels somewhat irregular. Patient's general health was good in every way except the migraine. Physical examination negative. V. in O. D. 20/30; V. in O. S. 20/40. Under a mydriatic O. D. 20/50; w. + .67 D. ⌒ + .67 cyl. ax. 90° = 20/20 O. S. 20/50; w. + .67 D. ⌒ + .67 cyl. ax. 90° = 20/20. This full correction was given for constant wear. He went eight months without an attack, and this was undoubtedly caused by having his spectacle frame bent—changing the axis of his lenses. This was straightened and he had no further trouble until he broke his frame, when another attack occurred.

Case IV.—Intense morning headaches due to far-sightedness (hypermetropia), accommodative asthenopia for near work. Harold H., aged twelve years; school-boy, American. Both father and mother far-sighted. Patient was a devoted student, ambitious to progress in his school work. I attended him for some months for headaches that would awaken him during the early morning hours, causing such intense pain that he would cry for hours. This condition persisted in spite of medication, regulation of diet and correcting a constipated tendency, until it was about decided on by his parents to take him out of school, although his physical condition was vigorous and his health otherwise uniformly good. Before taking this step the eyes were examined; V. in O. D. = 20/30 w. + 1.25 = 20/15; V. in O. S. = 20/20 w. + 1.50 = 20/20. Under a mydriatic 20/70 in each eye w. + 1.75 D. = 20/20. The correction given being +1.50 D. for use in near work which completely relieved him. He improved so rapidly that he gained ten pounds in weight within six months, and school-work was extremely easy for him subsequently. I have seen him within a week. He is about to graduate. It is now three years since this examination was made and he informs me he had never been troubled since with his former affliction. He uses his spectacles for studying only.

Case V.—C. M. D., aged thirty-six years, American housewife, married. Has neuropathic antecedents. Patient was referred to me by her family physician in April, 1899, for an examination of her eyes. She was a well-nourished woman with a good personal history. She was given to emotional states. The summer previous she became interested in spiritualism and concluded with an attack of grave hysteria, amounting to actual mania for several days and requiring restraint and the administration of the most powerful sedatives. She was sent to the mountains soon after to recuperate, but owing to a cardiac lesion was in no wise improved and returned in an exhausted state in which she remained, a semi-invalid, for months. She formerly had some pelvic disease, laceration of the cervix and perineum; the cervix was repaired, but the relaxation of the pelvic floor still causes a retroversion and chronic constipation. This latter condition has been fairly well taken care of by a well adjusted pessary. She complained of pains in her temples and eyes, with fatigue on using them, congestive occipital headaches and uncontrollable nervous spells. V. in O. D. 20/70 w. + .62 ⌒ + 1.00 ax. 75° = 20/20; V. in O. S. 20/30 w. + .62 ⌒ + 1.00 ax. 110° = 20/20; under a mydriatic O. D. 20/100 w. + 2.25 ⌒ + 1.00 ax. 75° = 20/20; O. S. 20/100 w. + 2.00 ⌒ + 1.00 ax. 110° = 20/20. After mydriatic had passed off she accepted O. D. + .75 ⌒ + 1.00 ax. 75°; O. S. + .75 ⌒ + 1.00 ax. 110°, and these were given for constant wear. She had a slight (¼°) R. hyperphoria and 4° esophoria in distance with 7° in accommodation. Prismatic exercises soon overcame this manifest, and together with her glasses she has almost perfect freedom from all her old nervous complaints. She has not had any headaches or fainting attacks since wearing her glasses. Her physical condition is much improved in lessened muscular relaxation; better color, heart's action and general health.

Case VI.—Neurasthenia with hysterical attacks in a male, depending upon errors of refraction superinduced by nervous shocks and excitement. F. H. H., aged twenty-six years, Austrian, single, electrician. Family history good. Personal history negative as to specific diseases. Has had robust health. Had malaria and brain fever in South Africa. Has led a life of excitement, following the occupation of electrician for different theatrical troupes in different parts of the world. Wished to enlist in the United States Army at the outbreak of Spanish war. Was examined and refused, but determined to enter and afterward succeeded in getting into United States artillery. In May, 1898, he received a severe fright from a flash of light in short circuiting a 110-volt current in a large Newark establishment. This produced a temporary blindness for three hours with profuse lacrimation. He was very much frightened. This, together with the disappointment of not getting into the army, determined him to go home to Carlsbad, where he arrived early in May. His father put him in the care of an eye specialist who prescribed glasses for him. He had some trouble from the glare of sunlight on the water while crossing the ocean, which was the first difficulty he had ever experienced with his eyes. He wore the glasses for a time, his eyes feeling better. He returned in June and entered the artillery service of the Government. In August he had trouble again with his eyes at target practice. While shooting the target would vanish, the white and black became mixed, which made him nervous. A few days after he became much agitated while standing in line with the artillery facing the sun and a reflected glare from the water. The moving of the rifles in practice exercises in this glare and sunlight brought on an uncontrollable nervous attack with pain in the base of the brain, blepharospasm, headache, nausea and "spectra" before his eyes. He was taken to the infirmary, being unable to perform his duties. Owing to no outward evidence of any inflammation of the eyes, his companions jeered him almost into a frenzy. The post surgeon, not being an oculist and always suspicious of malingering in the men, not finding any physical evidence of his nervousness, the ocular condition remained unrecognized. He became thoroughly incapacitated for duty and instead of going to the front was sent to one of the convalescent homes for sick soldiers instituted by that good and generous woman, Miss Helen Gould. He was treated there for neurasthenia with drugs only, and seen by an oculist who diagnosed hyperemia of the retinæ. A transference to another home brought him under my observation. I thoroughly examined him and finding no physical cause for his neurasthenia, he being in perfect physical health, I was attracted to his eyes by the fact that he choose dark corners of the sitting-room, avoided the lamplight and pulled his cap well down over his forehead when out-of-doors. Upon questioning him, I elicited from him this interesting history. I had him visit my office where I thoroughly examined his eyes. V. in O. D. 20/100 w. + 1.25 D. = 20/40; V. in O. S. 20/50; accepted no glass. Under a mydriatic: V. in O. D. 20/200 w. + 2.25 D. ⊂ + 2.25 ax. 80° = 20/40; V. in O. S. 20/100 w. + .75 D. ⊂ + 2.25 ax. 65° = 20/30. Javal's ophthalmometer: R. E. $\frac{22.00 @ 80°}{24.50 @ 1.0°}$; L. E. same Retinoscopic examination confirmed this approximately. Ophthalmoscope showed cornea, lenses, and vitreous normal; retinæ hyperemic; nerves normal but hypersensative to light. With the correction, after mydriatic has passed off, he showed ¾° L. hyperphoria; 2° of exophoria in distance with 5° in accommodation. Muscles showed R. E. 30 × 6 × 1 : L. E. 30 × 6 × 2. No diplopia with red glass, and normal convergence. Treatment by full correction of the astigmatism and part of the hypermetropia. He remained under my care for a few weeks and improvement was rapid. His sleep returned within a week. The pain at the occiput disappeared at once. By Christmas he was entirely well.

In conclusion, it is apparent from my personal experience that there are many cases presenting nondescript ailments, due to some latent irritation to susceptible nervous centers, capable of reflecting impressions to organs easily deranged, that are indirectly dependent upon abnormal conditions of congenital eye defects in refraction and muscular imbalance. It is not supposed that most general practitioners can become experts in the detection of the obscure etiology of these conditions, yet it is a matter for consideration and to be thought of most frequently instead of passively or openly ignoring the work done in this field, which is beginning to be entered by investigators conscientious in their endeavors to seek the truth. It is a favorable sign of progress that those who but a few years ago looked upon the subject as a fad are not opposing it openly to-day. I have seen many patients who had suffered for years relieved in a few weeks' of treatment—some in a few days. There is no reason why people so afflicted should go on to acquire a chronic habit of nerve derangement, or a fixed and intractible nervous disease, if the primary and exciting cause can be discovered and is amenable to treatment; and it is for this plea that this article is submitted for thought and reflection to those who so frequently meet these cases, *i. e.*, the general practitioners.

The following case is of interest in illustrating what may be accomplished in restoring some measure of function to a useless eye and correcting a deformity:

Miss J. M., aged twenty years. History of eye trouble on maternal side; near-sighted astigmatism in right eye and far-sighted astigmatism in the left eye, both compound, complicated by a divergent squint in right eye and a resultant amblyopia exanopsia. V. in O. D. 3/200 w—1.25 D. ⊂ — 2.75 cyl. ax. 180° = 20/200; V. in O. S.

20/40 w. + 1.50 D. ⌒ + .50 cyl. ax. 90° = 20/20; Javal's ophthalmometer = R. E. $\frac{23.75 @ 90°}{25.50 @ 180°}$; L. E. $\frac{24.00 @ 90°}{25.00 @ 180°}$ Retinoscopy and the ophthalmoscope confirmed these findings. Binocular single vision was possible only with a 20° prism base in over the right eye and 7° pr. B. down over the left eye. She fixed entirely with the left eye. Spectacles were given for constant wear correcting fully her refraction, and a grab front worn over these with prisms partly correcting the muscular defects. Supplementing this she was directed to wear a blinder over the good left eye for one or two hours twice a day and go about as usual to stimulate the function of vision in the amblyopic right eye. With these corrections and exercises she soon learned to use this eye to a considerable extent. Weekly the prisms were increased until she was wearing 8° B. in over right eye and 4° B. down over left eye. A continuation of this treatment for four months showed a decided improvement in vision in distance in readily and quickly recognizing the 20/200 letters or the second image of the candle; while at reading distance at first only certain letters in No. 14 Jager types were seen whereas at this time she read sentences in No. 11. I then made a complete tenotomy of the right externus, correcting the manifest squint, and six weeks later a partial tenotomy of the superior rectus of the left eye for the hypertropia, getting rid of this latter condition and reducing the exotropia more than one-half. A subsequent advancement of the right internal rectus is under advisement. The improvement in the appearance of the patient from a cosmetic point of view is most marked and satisfactory. From a tilting sidewise of the head and an eye mostly in the outer canthus, she now carries her head straight and has two parallel eyes. The aim in this case in undertaking treatment had been, first, to restore the function of vision in a blind eye and to make it to some extent useful in case the sound eye met with an accident, and, secondly, to correct an existing deformity in the divergent strabismus. Improvement is continuing in the betterment of visual acuity and it is reasonable to hope for still more.[1]

PRESENT STATUS OF INTERSTATE RECIPROCITY CONCERNING LICENSES TO PRACTISE MEDICINE.

By EMIL AMBERG, M.D.,
OF DETROIT, MICHIGAN.

(Continued from page 652.)

18. *Kansas.*

Answer to Question 5. Yes.

Answer to Question 6. We would.

Answer to Question 7. A congress composed of representatives of all the State Boards of Health in the United States might possibly be able to formulate some plan of action.

A better way, perhaps, would be to appoint a committee and authorize it to select the best parts of the several laws of the different states, and, from these selection compile a law, submit it to the Boards of Health in the United States for approval. (Signed) W. B. SWAN.

19. *Kentucky.*

No one can begin to practise who has not graduated from a recognized college requiring attendance upon four courses of lectures and meeting the other requirements of the American Medical College Association. Until there is a far more rigid enforcement of similar laws in other states of the Union it is not the intention of this Board to take any steps looking to interstate reciprocity.

(Signed) J. N. MCCORMACK.

20. *Louisiana.*

The Board, individually, is in favor of entering into an agreement which will recognize certificates from other Boards requiring the same standard as the Louisiana Board, but the Louisiana law requires all applicants to stand a written examination, and I do not see just now how this can be overcome. However, I will present the matter to the regular meeting of the State Society with the view of overcoming all obstacles.

(Signed) H. S. COCRAM.

21. *Maine.*

Representatives from all the Boards in New England met at Boston February 1, 1900, and after a discussion it was the unanimous opinion that radical changes in the laws are necessary to enable even the New England States to reciprocate in examination and registration. The desirability of this was conceded by all, etc.

(Signed) A. K. P. MESERVE.

22. *Maryland.*

Replying to your request of recent date, I beg to say that it is not our purpose to do anything at all with "Interstate Reciprocity for the License to Practise Medicine." Attempts to secure desirable modifications in the law came near destroying all law on the subject. We regard the present control of the stranger who desires to come into our gates as very satisfactory, and venture to commend it to others who really desire something good.

(Signed) J. MCP. SCOTT.

23. *Massachusetts.*

(See Maine.)

24. *Michigan.*

Part of Law: "The applicant shall be registered and given a certificate of registration if he shall present a certified copy or certificate of registration or license which has been issued to said applicant in another state of the Union where the requirements for registration shall be deemed

[1] A shortening of the right internus and a second complete tenotomy of the externus have resulted in perfect orthophoria, abolishing completely the diplopia and correcting the divergent squint.

by said Board to be equivalent of those of this Act. Provided such state shall accord a like privilege to holders of certificates from this Board. The fee for registration from applicants of this class shall be ten dollars."

25. *Minnesota.*

The physicians of this state are, I believe, beginning to see that reciprocity is desirable in the way of medical certificates. As secretary of this Board I shall ask that some provision be made in our next medical bill, which we propose to introduce at the next session of our legislature, in January, 1901.

(Signed) John B. Brimhall.

26. *Mississippi.*

Answer to Question 5. I would consider such a proposition.

Answer to Question 6. I will bring the matter before my Board at its next meeting, and, if so instructed by it, will gladly cooperate with you. (Signed) J. F. Hunter.

27. *Missouri.*

Answer to Questions 5 and 6. Yes.

Answer to Question 7. We believe that this is the only way to really succeed in advancing and maintaining the same, in both medical education and legislation, and we offer our hearty cooperation in an effort of this kind.

(Signed) E. L. Standlee.

28. *Montana.*

The Medical Practice Act of Montana provides that all applicants shall pass the Board of Medical Examiners' examination. Nothing has been done by us looking toward reciprocity, and no particular intention is evident.

(Signed) Wm. C. Riddell.

29. *Nebraska.*

Answer to Questions 5 and 6. Yes; but few states have as good a law as Nebraska.

Answer to Question 7. In my opinion our only hope is government recognition and control over medical education. Anything else is probably hopeless so far as securing a uniformly high standard is concerned. What could be done with Missouri, and many other Southern states?

(Signed) B. F. Crummer.

30. *Nevada.*

Answers to Questions 5 and 6. Yes.

(Signed) S. C. Gibson.

31. *New Hampshire.*

(See Maine.)

Part of law: "Applicants examined and licensed by other State Examining Boards registered by the regent as maintaining standards not lower than those provided by this chapter, etc., etc., may, without further examination, on payment of five dollars to the regent and on submitting such evidence as may be required, receive an endorsement of their licenses or diplomas, conferring all rights and privileges of a regents' license issued after examination.

32. *New Jersey.*

Part of Law: "Certificates of examination and license issued by the Board of Regents of New York, and by the Medical Councils of Pennsylvania and Delaware, based upon examination by the respective Examining Boards of those States, may be endorsed at any time by this Board. Blanks for this purpose must be obtained from the Secretary, and, when properly filled out and returned for filing, must be accompanied by a certified check, or postal money order, for the regular fee of fifty dollars."

33. *New Mexico.*

Answer to Question 5. Yes, if we did not have to recognize a lot of newspaper advertisers who hold licenses in other states.

Answer to Question 6. Yes.

(Signed) T. P. Martin.

34. *New York.*

Part of law: "Applicants examined and licensed by other State Boards registered by the regents as maintaining a standard not lower than those provided by this article . . . may, without further examination, on payment of ten dollars to the regents . . . receive from them an endorsement of their license."

The attorney-general, the legal adviser to all the state departments, has decided that no discrimination should be made in the interpretation of this law whereby the licenses issued by other states could be endorsed unless the state itself observed a standard (both of its academic and in its examinations and tests) which was equal to that maintained by the officials having charge of such examinations in the State of New York. Because of that decision the State Board of Medical Examiners has up to this time been unable to recommend the indorsement of licenses conferred by other states, and, inasmuch as the law has also been held to apply to states of the United States only, the indorsement of licenses issued by foreign countries has also been impossible. The State Board of Medical Examiners is on record as being in favor of reciprocal action in connection with the indorsement of licenses as soon as the law can be so formulated as to make such a procedure possible without any discrimination against the interests of those who are educated and licensed to practise medicine within the borders of this state.

(Signed) M. J. Lewi.

35. *North Carolina.*

You will note that a license from another state only entitles to examination, just as a diploma from a college in good standing does.

We considered the reciprocity idea, but our standard is so much higher than it is in most of the states that, for the present at any rate, we

are afraid of it. We can see no objection to requiring a physician who wishes to practise in our state, coming from another state, to submit to the same conditions that we demand of our own people. I do not wish to throw cold water upon your work, but I do not think you can count on North Carolina for a good many years to come.

(Signed) Chairman Com. on Legislation.

36. *North Dakota.*

I would say that all the members of our Board are in hearty accord with the reciprocity movement, and that when the measure becomes generally adopted we will be found in line. We expect to prepare for it by having the necessary amendment to our law passed at the coming session. (Signed) H. W. Wheeler.

37. *Ohio.*

Part of Law: "Provided further, that the Board may, at its discretion, dispense with an examination in the case of a physician or surgeon duly authorized to practise medicine or surgery in any other state, territory, or the District of Columbia, who may desire to change his residence to Ohio and who makes application on a form to be prescribed by the board, accompanied by a fee of fifty dollars, and presents a certificate or license issued after an examination by the medical board of such state, territory or the District of Columbia, accorded only to applicants of states, territories or districts whose laws demand qualifications of equal grade with those required in Ohio; but such examination shall not be dispensed with unless under the law and regulations of the state, territory or District of Columbia, equal rights and privileges are accorded to physicians and surgeons of Ohio holding the certificate of the board, who may desire to remove to, and practise in such state, territory, or the District of Columbia."

38. *Oklahoma.*

I believe it would be possible to enact a law in this territory imposing interstate reciprocity. The same would be agreeable to the medical profession. If this is ever achieved Oklahoma Territory would be one of the first political divisions to fall into line with the improved era of medical legislation. (Signed) L. Haynes Buxton.

39. *Oregon.*

As previously stated to you, this Board, under its present law (a copy of which I inclose) can do nothing in this matter. However, the Board is favorable toward such a law.

(Signed) Byron E. Miller.

40. *Pennsylvania.*

The Medical Council of Pennsylvania recognizes licenses issued by the State of New York and the State of New Jersey.

(Signed) Nathan C. Schaeffer.

41. *Rhode Island.*

(See Maine.)

42. *South Carolina.*

Our Board is with you in our wish to enter into reciprocity with other State Boards. . . . We were afraid to inject new matter into the discussion at this time, but will work for the reciprocity feature when expedient.

(Signed) S. C. Baker.

43. *South Dakota.*

So far as I am able to state nothing has been done officially in regard to professional reciprocity, but I have heard the opinion of prominent medical men in our state to the effect that they were in favor of this movement and would cooperate with any and all influences to bring it to a satisfactory accomplishment.

(Signed) A. E. McClough.

44. *Tennessee.*

Our law has been so emasculated and altered that we are almost discouraged, and, unless the next legislature improves it, the Board will resign. This being the case, nothing has been done in regard to "Interstate Reciprocity." We could not ask any state to accept our certificates. They are only certificates of holding a diploma from some Tennessee college. The law now requires an examination of only those who have been so unfortunate (?) as to not have graduated in a Tennessee college, or a non-graduate.

(Signed) T. J. Happel.

45. *Texas.*

I am sorry to say that the state of Texas has no State Board of Medical Examiners; we have so-called district boards, but under existing statutes their organizations and operations are farcical, as they often license men without diplomas, and commit so many irregularities that we would be better off without them. The State Association has labored so far without success to obtain the enactment of an adequate law. We expect, however, to continue our efforts.

(Signed) H. A. West.

46. *Utah.*

The law of our state must be amended to allow interstate reciprocity, which, no doubt, will be done in the near future.

(Signed) J. F. White.

47. *Vermont.*

All the medical examiners of the New England States are to hold a meeting semi-annually with the idea of uniformity in examinations and interstate reciprocity. See Maine.

(Signed) H. C. Tinkham.

48. *Virginia.*

Just what action the Board will take in regard to accepting other state certificates I am unable to say until after our June meeting, but suppose we will exchange certificates with all other boards having the same requirements as ours. I am strongly in favor of interchange of certificates among the states, and shall use all my in-

fluence to obtain this very desirable result with those states who wish to exchange and whose requirements are in every way equal to ours.

(Signed) R. S. Martin.

49. *Washington.*

Answer to Question 5. No. It might tend to establish a "Medical Colony" in South Dakota, to the detriment of the already established "Divorce Colony," which should stand alone as a monument to the ambition of a growing state.

Answer to Question 6. Yes.

Answer to Question 7. Will submit the matter to the Board at next session.

(Signed) W. G. Tucker.

Note.—This answer has been classified as unfavorable, in the third committee report.

50. *West Virginia.*

Answers to Questions 5 and 6. A few years ago we made an effort of this character to the states contiguous to this, and they declined, since which we've rested. Our legislature, having made an effort to this end several years ago and having been snubbed by contiguous legislatures (save Maryland), would feel disposed to wait further action on their part.

Answer to Question 7. After some action of legislatures of adjoining states in the matter, our Board would be ready to act, and might have something to suggest. Not till then.

(Signed) A. N. Barbee.

51. *Wisconsin.*

Part of medical law, 1898: "Any practitioner of medicine holding a certificate from any other State Board imposing requirements equal to those established by the Board provided for herein may, on presentation of the same with a diploma, be admitted to practice in this state without an examination, at the discretion of the Board, on payment of the fee."

The project of a National and State League of State Licentiates with reciprocal arrangements with states of equal standards has been frequently considered by the Board. A strong effort will be made at the meeting of the next legislature to advance our standard to a state examination of all graduates.

(Signed) H. M. Ludwig.

52. *Wyoming.*

We, as a Board, have made it a rule to issue no license to practitioners, except in compliance with the requirements of our own laws.

Owing to the fact that some states which have good medical laws seem to have Boards that are very lax in enforcing their requirements, we have deemed this course not only advisable, but absolutely necessary in regulating this matter in our own state. So long as the authority to grant a license is vested in the members of the Board to the degree as it is in many of the states, we do not feel that we can consistently enter into any interstate reciprocity, even if we had the legal power to do so. This board has just received a personal recommendation from the president of the ———— State Board of Medical Examiners, in behalf of a man whose sole claims for recognition was a diploma issued by one of the most disreputable "mills" in the country. So long as State Boards are so utterly indifferent in performing their duties as the one above mentioned (the applicant is a registered practitioner in ————) we are distinctly opposed to reciprocity with such people. It is needless to say that the applicant was refused a certificate. (Signed) Geo P. Johnson.

These answers speak for themselves. There is not a single political division, I think, which does not express the desire for an improvement, be it in its own jurisdiction or in that of another part of the Union.

The medical profession, and the people, are under great obligations to all these writers, also to all members of the profession and to all others who work for a betterment of the conditions under consideration.

I, for my part, take occasion in this place to express hearty thanks to all who facilitated our work.

As to the future steps to be taken, permit me to offer the following suggestions:

It is advisable that all local medical societies in the United States appoint committees to study the question. The various state and territorial medical societies should appoint a central committee which should be in touch with the committees of the local societies and also with a committee to be appointed by the American Medical Association or by the Section on State Medicine. The latter committee should be in constant touch with a committee of the National Confederation of the State Medical Examining and Licensing Boards.

Besides the advantages of having committees which could work continuously one with another, the committees at the same time could spread information. They thus would be educational factors of no little importance. Meanwhile, the various societies in the United States should have the reciprocity clause added to their medical laws.

It also would be advisable, as I pointed out a few days ago, that the certificates of medically stronger states and territories be accepted by the weaker states or territories, without the stronger division accepting the certificates of the weaker division. This point has also been brought forward by the secretary of the American Academy of Medicine, Dr. McIntire. I defended the idea quite a while ago in Michigan. My suggestion was not accepted, however, for reasons which, I think, are of local interest, although it was in my opinion an injustice to enact the law as it stands now. A well-known United States official, in a communication to me, calls the clause in the Michigan law an exceedingly unfortunate one. We see that New Jersey and Pennsylvania set us a good example in this respect.

The various political divisions will, we are

sure, encourage the movement, and lend a helping hand to establish a condition of affairs worthy of the present age. The best qualified physicians should be available to all, and the medical profession will not cease in their efforts until the point is reached when the title "doctor of medicine" in any place in the United States gives the guarantee that the bearer complied with those requirements which the present state of medical science demands.

If we view interstate reciprocity for the license to practise medicine from our standpoint as physicians, as citizens, and as men, we must admit that a more timely and more humane proposition has never been before the medical profession or before the people of the United States.[1]

MEDICAL PROGRESS.

Thiocol in Tuberculosis.—J. Braun (*Klin. therap. Woch.*, Sept. 23, 1900) has found that most of his patients rebel against the disagreeable taste of creosote and guaiacol and therefore recommends thiocol, which, while it possesses an equal efficiency, is more pleasant to take, since it possesses only a slight salty and bitter taste which does not persist. It is indicated especially in advanced cases with good pulse and may be given in several doses of one-half to one gram daily with none but encouraging results.

The Treatment of Scabies.—Of the many agents recommended in the treatment of this distressing condition the most widely used and generally approved are probably balsam of Peru, styrax, betanaphtol, tar, petroleum, and sulphur. Good results are to be attained by the use of each one of these, but each one also has its distinct contraindications in its compromising odor, property of staining the linen or irritative action on the skin or on the internal organs after absorption. By a careful series of comparative observations made by immersing acari from infected patients in various parasiticide preparations Richard Sachs (*Deutsche med. Woch.*, Sept. 27, 1900) determined that the greatest efficiency is manifested by styrax, betanaphtol and a new synthetic product to which the name of peruscabin has been given. In composition this represents the active constituents of balsam of Peru, being a mixture of cinnamein, styracin and cinnamic acid; it is odorless, non-staining and non-irritating to the skin or internals organs. It is best applied diluted with three parts of castor oil and should be rubbed over the entire surface three times in thirty-six hours. At the end of this time the underwear and linen are changed and three or four days later a full bath is taken. Thirty-five cases were successfully treated in this way, the cure being absolute and no irritative or other untoward effects being produced even in patients already suffering from eczema, dermatitis, etc. The remedy is especially to be recommended for use in children, in debilitated patients and in those having other complicating skin diseases.

Digitalis, Strophanthus and Diuretin.—The best authorities differ widely in their opinions relative to the comparative action of these drugs as diuretics in health and in disease. J. A. MacCaren (*Med. Chron.*, Sept., 1900) has conducted a series of experiments upon himself and has also accumulated some valuable clinical data from hospital patients. During a period of twelve days he took on the fifth, sixth, seventh and eighth days an average of a dram and a half of tincture of digitalis each day. On the seventh day toxic symptoms appeared and diuresis set in. There was an increase in the amount of urine passed from 40 to 47 ounces per day, and an increase in the excretion of urea from 507 to 521 grains. No diuretic effect was obtained from the infusion, but no toxic symptoms appeared. No diuresis was obtained from the use of eighty-five minims of tincture of strophanthus taken during four days, or from two hundred and seventy grains of diuretin taken during three days, although marked toxic symptoms appeared in both instances. In disease "spontaneous diuresis" is believed to be responsible for many of the good effects attributed to drugs. Rest in bed and a regular diet will alone cause diuresis in sixty per cent. of cases in from two to five days. The urea excretion is similarly increased. In 26 cardiac cases treated by digitalis an increase in excretion of solids and fluids took place in 22 cases, and the best results were obtained from the tincture, ℥ xv every four hours, or from Nativelle's granules, one three times per day. Out of 13 cases in which strophanthus was used 8 showed diuretic effects, though not so marked as from digitalis and much more disagreeable gastro-intestinal symptoms followed. Diuretin increased the urine in 6 out of 12 cases, its advantage being the rapidity of its action, but its toxic symptoms were more marked than digitalis and its effect less prolonged. In Bright's disease, however, it acts more favorably than digitalis or strophanthus. In cardiac dropsy digitalis is the drug *par excellence*, being more powerful, less toxic and more certain than the other drugs.

Faucial Inflammation Resembling Diphtheria.—A faucial condition very similar to that due to the Klebs-Löffler bacillus is sometimes observed in patients who do not present the clinical symptoms of diphtheria and do not respond to the treatment of that disease. F. Nilly (*Med. Chron.*, Sept., 1900) reviews four cases and points out the features which distinguish them from diphtheria. (1) The local lesion is more gangrenous in nature, and the ulceration exposed by the separation of the slough is more constant and extensive. (2) The disease is of a more febrile nature and delirium is not uncommon.

[1] Read before the Section on State Medicine of the American Medical Association.

(3) Paralyses do not occur. (4) Recovery, when it occurs, is more rapid and the heart is less affected. (5) The Klebs-Löffler bacillus is present only in small numbers, if at all. (6) Streptococcus pyogenes is the preponderating organism. (7) The diphtheritic antitoxin does not affect the disease. The local appearance is not so characteristic as to be diagnostic. The temperature range, however, is somewhat significant. The author states that a case of apparently membranous faucial inflammation exhibiting a temperature of 103° F. for two consecutive days is probably not one of true diphtheria. This condition, however, is liable to run a constantly high temperature for several days. Signs of cardiac weakness, so common during the prolonged convalescence from diphtheria, are not present in this pseudo-form. So far as the bacteriology of these cases is concerned it is impossible to draw any conclusions from so little material. Several examinations failed to demonstrate the presence of the bacillus diphtheriæ in two of the cases and they were found in very small numbers in two others. The streptococci pyogenes were present, however, in large numbers, but on account of their omnipresence no conclusions can be drawn.

Obstruction of Common Bile-Duct.—The symptoms vary, says J. B. Deaver (*Phila. Med. Jour.*, Oct. 6, 1900), according to the character and cause of the obstruction of the duct. Acute obstruction gives sudden onset of colic, nausea or vomiting or both, pain, tenderness and in some instances collapse and jaundice. Colic in this obstruction is due entirely to the effort of the duct to expel the foreign body and is analogous to the colic of appendicitis. When the stone is situate near the duodenal end of the duct, the cramps may be continuous and cease only when the calculus either drops into the gut or returns into the duct, after the manner of a ball in a ball valve. Coincident with the seizure of colic is pain in the region of the liver often referred to the epigastrium, the umbilicus, the right shoulder and the right chest-wall. A normal at the midpoint of a line joining the umbilicus and the tip of the ninth rib will correspond quite well to the course of the common duct and over this should lie most of the pain and the tenderness. This tenderness is always very pronounced, even upon very gentle palpation and the presence of cholecystitis accentuates it to a large degree. Rigidity of the right rectus muscle is also a very early sign obtainable by the slightest touch of the finger-tips. Such delicate examinations reveal more than almost any other one means. Marked fixation of the flat muscles in the upper right quadrant of the abdomen is more commonly a later development in the disease. Nausea and vomiting are purely reflex. The temperature is also an important symptom. In an acute case a rise shows the advent of inflammation. In a chronic case the intermittent form usually indicates gallstones. Collapse may be either only a reflex or may forerun rupture of the duct. Jaundice is not a constant symptom in the acute cases, although the obstruction may be complete, as in acute edema of the mucosa and arrest of a calculus. But permanent closure of the bile-passages always has jaundice and in the case of cancer is always progressive. A differential diagnosis of the cause of the obstruction should always be tried. The chief points therein are: Previous attacks of bilious colic associated with pain and tenderness in the region of the liver, with or without jaundice; vomiting and its coincidence with or priority to the colic; attacks of jaundice following each attack and present soon after the pain; recurrent attacks of colic with jaundice and an irregular fever. To distinguish between stenosis and other non-malignant causes of obstruction, without exploratory laparotomy, would be an impossibility. The most common cause of malignant stenosis is cancer of the head of the pancreas. This neoplasm gives progressive loss of flesh and strength, digestive disturbances, absence of characteristic colic, pain, no temperature elevation and sooner or later a palpable tumor in the epigastrium. The treatment is medical and then either preventive or expectant or surgical and then either palliative or curative.

Suprarenal Extract and the Heart.—Much has been written about the so-called constitutional effects from the internal use of the suprarenal extract, but very little reliable clinical data have yet been furnished. S. Floersheim (*N. Y. Med. Jour.*, Oct. 6, 1900) has experimented with several normal and abnormal cardiac cases with the idea of determining what effect, if any, the drug has upon this important organ. When the powdered suprarenal is placed on the tongue, mixed with the saliva and chewed thoroughly, he has found it to show its effects within ten seconds; at other times it has required ten minutes. He has not seen a case with a weak irregular pulse in which the effects were not manifest within ten minutes. Although the action of the drug is very rapid, its effects have passed off as rapidly, and the changes in the heart's action never seem to be at all permanent. Upon the normal heart no influence has been detected after the administration of this drug, and the normal pulse in cases of organic disease is likewise unaffected. Dr. Bates believes it to be the most powerful known stimulant of the heart, but admits that its action is only temporary.

Etiology of Gall-Stones.—F. C. Shattuck (*Phila. Med. Jour.*, Oct. 6, 1900) enumerates the well-known causes of biliary calculi as: (1) Cholesterin, bilirubin calcium precipitated by changed reaction, bacteria of various types, foreign bodies. Frerichs and Naunyn give stasis, catarrh and changed reaction as the three chief causes. (2) Age, very uncommon in childhood, rare under thirty, somewhat common between thirty and sixty, very usual after sixty years. (3) Females suffer from them in the ratio of

four to two. (4) Anything predisposing to stasis; here are felt the influence of age with its less active or slightly pathological metabolism, of sex with the sedentary life of woman, of enforced quiet in heart-disease, of confinement among the insane, of altered anatomical relations in floating kidney, gastroptosis, pregnancy and lacing. (5) Bacteria are very important. Modern methods show (*a*) sterile foreign bodies do not cause gall-stones, though a sterile gall-stone may be penetrated at least by the colon bacillus; (*b*) the contents of the hepatic and cystic ducts are usually sterile; (*c*) those of the common duct are usually infectious directly from the duodenum; (*d*) gall-stones have been experimentally produced; failures have followed the use of virulent cultures, while attenuated cultures with or without foreign bodies have succeeded; (*e*) bacteria are found in a very considerable number of gall-stones; (*f*) the clumping peculiarity of the typhoid bacillus seems to be a very active factor and has succeeded experimentally; (*g*) the bacillus coli communis and bacillus typhosus are the most potent generators of biliary calculi.

Drainage of the Biliary Passages.—The indications are alike for operative interference and for drainage is the opinion of J. E. Summers, Jr. (*Phila. Med. Jour.*, Oct. 6, 1900), and are these: (1) Acute or chronic cholecystitis not amenable to medical treatment and occurring either independently or as complications and sequelæ of infectious disease. (2) Gall-stones in the bladder or ducts producing frequent attacks of colic with or without jaundice. (3) Palpable enlargement of the bladder, especially if pus is probably present. (4) Suspicion of phlegmon, ulceration or gangrene of the gall-bladder. (5) Of puncture, perforation or rupture of it. (6) Suppuration in the ducts of the liver. (7) Signs of stricture or foreign body occlusion of the ducts. (8) Of neoplasms or adhesions hindering the normal outflow. (9) Intestinal drainage is indicated when external is impossible. In order to facilitate the closure of the drainage tract from the bladder he follows this technic: The bladder is sutured to the parietal peritoneum in the usual way, but about three-quarters of an inch back from the wound in it. Mattress sutures are then placed in this manner. The first loop penetrates all the muscle layers of the wall, emerges just within the suture line above, then pierces at this point all coats of the bladder and, finally, passes again through all the bladder layers near the margin of the bladder wound. The second loop is just the reverse of each step. When tied, the free margin of the bladder is double upon itself so that the mucosæ are in contact and the peritoneum forms a complete margin of the bladder wound. When the drain is out, rapid adhesions are claimed to occur. Chromated gut is used.

Typhoid in Children.—The statistics of one hundred cases under fifteen years of age are given by A. D. Blackader (*Montreal Med. Jour.*, Sept., 1900). Four only were under two years, 13 between two and five years. In 13 cases the onset was sudden with marked gastro-intestinal disturbances. As initial symptoms headache occurred in 68 cases, vertigo in 19, anorexia in 49, chilly feelings in 12, chills in none, vomiting in 18, diarrhea in 36, constipation in 59. Fulness of the abdominal parietes was noted in 48 cases, abdominal pain in 33, tenderness in 15, epistaxis in 23, tonsillitis in 6. The step-like ascent of temperature at the onset was noted in only 8 cases. After the first week the temperature in most cases was markedly remittent, the evening temperature reaching normal, however, about the end of the third week. In 19 cases the fever reached 105° F., in 16 the temperature remained low and the fever lasted under two weeks. The spleen was palpable in 70 cases. Rose spots present in 55, tenderness in left hypochondriac region in 18. A diffuse erythema of neck and chest during the first week was noted in 2 cases. No severe hemorrhage occurred, but in 4 cases there were traces of blood in the stools. In 19, sonorous and sibilant râles were present at the bases of both lungs. A soft, systolic murmur at apex or base was heard in 22 cases. Drowsiness or semistupor and restlessness or sleeplessness occurred about equally; 18 cases had mild nocturnal delirium, and 1 only developed the typhoid state. There were cases with otitis, periostitis, and furunculosis. The Widal reaction was carefully sought for in 43 cases, in 3 of which it failed. It varied in its appearance from the fourth to the twenty-eighth day and once did not appear until convalescence had set in. The treatment consisted mostly in cool baths, beginning at 90° to 85° F. and lowering to 85° to 75° F. In 30 instances systematic sponges were given every three hours with water at 70° F. The stimulants used were whiskey or brandy, administered freely in some cases, and strychnine. The chief dietary was milk, diluted, if necessary. The author believes that alcohol is a rapidly and easily appropriated food. He advocates the use of the cool bath once or twice a day even after the pyrexia falls below 102° F. This procedure is not to be continued indefinitely however.

Jaborandi.—H. A. Jowett (*Brit. Med. Jour.*, Oct. 3, 1900) has contributed an important addition to our knowledge of the alkaloids of Jaborandi. Gerrard and Hardy isolated pilocarpin and later pilocarpidin and jaborin were isolated. Jowett, however, fails to find any trace of an alkaloid like jaborin and concludes that in true jaborandi leaves no such alkaloid exists. He has confirmed Marshall's report on the presence of an isopilocarpin, isomeric with this alkaloid, and identical with the alkaloid formerly named pilocarpin by Petit and Polonowsky. This leaves the alkaloids from true jaborandi to be pilocarpin, isopilocarpin and pilocarpidin.

THERAPEUTIC HINTS.

Urethral Chills.—To ward off chills following internal urethrotomy or the use of sounds, Weir prescribes:

℞ Morph. sulph.... .006 gm. (gr. 1/10)
Tinct. aconiti.... .15 cc. (♏ ij)
Ol. gaulther....1.0 cc. (♏ xv)

Dormiol.—For the administration of this new hypnotic compound of chloral and amylene hydrate, the following formulæ are recommended:

℞ Dormiol, 10% solution..100.0 (℥iiiss)
Syr. raspberry.....ad. 120.0 (℥iv)

One to two tablespoonfuls at bedtime.

℞ Dormiol, 10% solut..... 90.0 (℥iij)
Ext. licorice..... 4.0 (℥i)
Syrup .....ad. 120.0 (℥iv)

Shake before using. A tablespoonful at bedtime.—*Merck's Archives.*

Amenorrhea.—Huchard orders that the lumbar region be rubbed, on retiring, with

℞ Chloroform ..... 10. (℥iiss)
Ether ..... 20. (℥v)
Spt. camphor..... 90. (℥iij)

This to be supplemented by mustard foot-baths, sinapisms to the internal aspect of the thighs, and vaginal injections of water from 105° to 120° F. As a tonic he gives

℞ Ferri et potass. tart..... 6.0 (℥iss)
Aloes socot..... 1.0 (gr. xv)
Ext. absinthii.....
Ext. artemisiæ.....aa. 2.0 (gr. xxx)
Ol. anisi..... 0.1 (gtt. iij)

M Ft. pil. No. 50. Sig., two after each meal.—*Journal de Médecine de Bordeaux.*

Intestinal Antiseptic.—

℞ Betanaphtol ..... 3.0 (gr. xlv)
Chloroform ..... 0.03 (gtt. xv)
Ol. ricini.....90.0 (℥iij)
Spt. menth. pip..... 0.02 (gtt. v)

A tablespoonful for an adult in port wine, beer, or sweetened black coffee; for a child, a teaspoonful.—*Journal de Médecine de Bordeaux.*

Whooping-Cough.—R. A. Lancaster recommends

℞ Tinct. belladonna...16.0-24.0 (℥iv-vj)
Spt. frumenti.....30.0 (℥i)
Phenacetin .....10.0 (℥iiss)
Fl. ext. castaneæ foliæ .....ad. 180.0 (℥vj)

M. Shake before using. From ten drops for a one-year-old child to a teaspoonful for a ten-year-old child every two to six hours.—*Jour. Amer. Med. Assoc.*

Inflation of the Middle Ear.—This, according to A. H. Buck, serves to push a drum membrane back to its normal position, and to give a kind of massage to the Eustachian tube and middle ear. There are three methods of inflation: (1) That of Valsalva, in which the patient holds the nose and distends the cheeks. It always makes congestion and may cause rupture of a small vessel in the ear, especially in old persons. (2) The Eustachian catheter, which is unpleasant to the patient, and by its hardness may irritate the Eustachian tube and retard the cure. (3) Politzer's method, in which a large rubber bag is connected with one nostril by a rubber tube and nose-piece. The patient is told to swallow, and as the thyroid cartilage rises, the bag is suddenly compressed. In the act of swallowing, the soft palate closes the pharyngeal opening of the nose, and at the same time the Eustachian tube opens, so that a maximum effect upon the ear is obtained.

Diuretic.—For an agreeable diuretic and to alkalize the urine, Peabody recommends that two solutions be kept on hand, as follows:

No. 1. Potass. acetat..... 25.0 (℥viss)
Potass. bicarb..... 12.0 (℥iij)
Aquæ .....ad. 240.0 (℥viij)
No. 2. Ac. citrici..... 10.0 (℥iiss)
Aquæ .....ad. 60.0 (℥ij)

Dilute with 60 ccm. (℥ij) of water 15 ccm. (℥ss) of No. 1-4 ccm. (℥j) of No. 2 and give in twenty-four hours.

Orthoform.—In nose and throat work, the reports of the use of this drug have been almost universally favorable. Brocq, however, has found orthoform sometimes irritating, and capable of exciting hyperemia and pruritus. In one case, a one-to-forty ointment caused swelling and redness lasting three weeks. Asam reports nine cases in which it produced inflammation, and Miodowsky observed a case of moist gangrene following the application of a five-per-cent. ointment.—*Year-Book of the Nose, Throat and Ear.*

Dislocation of Shoulder.—The rare backward dislocations of the humerus are best reduced in the following manner: The arm is raised to a right angle or the horizontal, extended, rotated, and then adducted, while at the same time the head is forced into the glenoid cavity by direct pressure from behind. If this is not successful, reduction is sometimes accomplished very easily by strong abduction of the arm with subsequent rotation inward, or by elevation of the arm and pressure of the head into the cavity.—*Tillmann's Text-Book of Surgery.*

Iodides in Locomotor Ataxia.—Roux, in a recent work on the sensory visceral derangements in tabes shows that iodide may irritate the stomach, alter the mucosa, and cause gastritis, with serious consequences. The pain is felt in the lower thorax, especially the left side, and may be severe; it is felt an hour or two after eating, increases gradually, and then disappears before the next meal. Vomiting may ensue, and persistence in the iodide may finally produce typical gastric crises. These are distinguished from true crises by their gradual onset and disappearance, by their development after gastric irritation or at the menses, and by their suppression with a milk diet and discontinuance of the iodide. —*Journal of Nervous and Mental Disease.*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinica Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 Fifth Avenue, New York.

SATURDAY, NOVEMBER 3, 1900.

THE ETIOLOGY OF YELLOW FEVER.

A new and fertile field for research made possible by the brilliant work of Ross and the Italian observers in connection with the theory of the propagation of malaria by the mosquito has recently been further extended by four American investigators, Reed, Carroll, Agramonte and Lazear (*Philadelphia Medical Journal*, October 27, 1900), to yellow fever.

The mosquito as a factor in the propagation of yellow fever is by no means a new conception; as far back as 1881 Carlos Finlay of Havana ingeniously discussed such a relationship. Since then it has been revived from time to time by various writers, but, until the researches by the American writers just named, no definite investigations have been undertaken.

Reed and his co-workers were able to study the effects of the bite of the *Culex fasciatus* Fabr. upon 11 non-immune individuals with 9 negative results to infect and 2 positive results. Based on these results they feel justified in the conclusion that the mosquito serves as the intermediate host for the parasite of yellow fever, and that it is highly probable that the disease is only propagated through the bite of the insect.

To a critical reader, it must be confessed, however, that the conclusions, *in toto*, are scarcely supported by the evidence presented. The number of unsuccessful results, and the possibility of other modes of infection hardly seem to be taken into any consideration. Moreover to conclude that the disease is only transmitted by the bite of the mosquito appears to us a veritable *tour-de-force* of the imagination; in the first place they fail to bring forward enough clinching evidence to make the demonstration wholly conclusive, to say nothing of the fact that they have excluded no other possible mode of transmission. At most it can only be said that the work presented does little else than prove suggestive for what may be one important mode of transmission.

Another part of their investigation relating to the presence of the *bacillus icteroides* (Sanarelli) in yellow fever cases is equally full of interest. Contrary to a number of favorable results by some careful workers these observers believe that the *bacillus icteroides* stands in no causative relation to yellow fever, but when present should be considered as a secondary invader in the disease. For our own part, considering the excellent work done on both sides of the question, we would prefer to regard the matter still *sub judice*.

A NOVELIST'S VIEW OF MEDICINE.

Ouida, that wise lady with the manlike mind, whose books many of us admire for their brilliant versatility, has lately launched a most unexpected diatribe against physicians and scientists in the *Humane Review*. It reads as though an incensed comet, whose tail a grave astronomer was endeavoring to measure, should say, "Cruel brother of creed-makers, you, who would measure my tail and express it in a formula, behold, I will measure its length upon your narrowing instrument," and with one sweep should smash his good telescope, and sail away thinking how smart it had been.

According to this article, the physician deliberately cultivates in mankind a terror of disease which renders him an easy prey to it and incidentally fills the physician's pocket. More deadly than the propaganda of the priest is the influence on the multitude of the scientist who "teaches men and women to see possible or probable death in every thing that approaches them," and leads them "to pass their whole existence in a stench of disinfectants." They are taught to "slink with fear of contamination from the rosy lips of a child and flee from the good-natured gambols of a merry dog."

Certainly it has been of some little value to disinfect after measles, to refrain from kissing a child with diphtheria, and to muzzle dogs that may have rabies. That narrowing cowardice, the deteriorating influence of which Ouida bemoans for the human race, does not work such ravages on the average human system as does any one of these curses which science has sought to mitigate. We are tempted to think that Ouida gets her science from the newspapers.

And then with an almost feminine lack of logic, she wants to know why the biologist and scientist do not lift their voices against war if they are really so anxious to save life, and concludes that it is only because the gold would not pour any faster into "the blood-stained apron of the licensed experimenter."

But Ouida knows something about medicine herself. She has had "personal experience of all the symptoms of 'angina pseudo-membranosa,'" and has several times seen a physician diagnose a disease as that, when she knew it was not that at all. We think we understand. Some professional man has not been duly impressed by her grasp of scientific subjects; may have intimated that "a little learning is a dangerous thing" or may have explained in a manner calculated to enlighten ignorance something that she knew perfectly well. What could be more odious? And what more natural than that biologists, scientists and physicians the world over should have their egoism and masterful exaggerations pricked by her forceful and discriminating pen!

THE BACILLUS PYOCYANEUS IN HUMAN PATHOLOGY.

Considering the important position that clinical bacteriology has assumed in the last ten years in its relation to practical medicine, it is surprising that more definite knowledge has not come to hand concerning a series of infectious processes incited by a group of organisms for a long time regarded as harmless to the human body. Of the whole number of bacteria belonging to this class, no single one possesses the same varied interest as the bacillus pyocyaneus. The history of its experimental achievements alone embodies some of the most absorbing themes of bacteriology.

Since the publication of the admirable researches of Charrin on this organism in 1889, some attention has been directed to the study of its relations to certain morbid phenomena encountered from time to time in human pathology. Systematic bacteriological examinations—unfortunately still the exception rather than the rule at the hospital bedside and in the post-mortem room—have brought forward sufficient evidence to establish at least a causative relation to a series of pathological lesions in the human subject. Among those most prominent in elucidating this chapter of human infections may be cited Charrin, Maggiora and Gradenigo, Calmette, Thiercelin and Lesage, Lartigau and several others.

Like the more important members of the pus-producing group of bacteria, the bacillus of blue pus may incite a wide range of different and unrelated processes. The observations of Martha and Maggiora and Gradenigo fix its relations to certain cases of purulent otitis media. In cutaneous and subcutaneous inflammations it has been met with in human beings, causing gangrenous processes, suppurative phlegmon, vesicular eruptions and exfoliative processes. Among the more common of the lesions of the respiratory tract are bronchopneumonia and pleuritis. G. Blumer demonstrated the presence of this bacillus in practically pure cultures in a case of acute angina clinically simulating diphtheria. Except in instances of general infection the circulatory system usually escapes; the bacillus pyocyaneus has, however, been isolated from valvular vegetations of the heart. Judging from the number of cases reported, urinary infection with this organism is relatively common; until very recently ascending pyocyanic urinary infection has not been recorded. A report of three such cases has just been contributed by Blumer and Lartigau (*N. Y. Med. Jour.*, September 22, 1900). The urinary lesions were those of inflammatory hyperplasia.

One of their cases is of particular interest from the chain of nervous symptoms presented. These were partial paraplegia and exaggerated reflexes succeeded by complete paraplegia, loss of reflexes, anesthesia and analgesia. No demonstrable cord lesions were present to account for these phenomena. This symptom-complex is of especial interest, owing to its similarity to that described in a case by Jadkewitsch, arising from similar infection.

By far the best known infections are those which relate to the gastrointestinal tube; for the most part this type of pyocyanic infection has been most commonly observed in infants. These have been so thoroughly studied by Neumann, Cadet de Gassicourt and Lesage, that little seems

wanting in that direction. In these days when the etiology of dysentery is exciting considerable attention the rôle of the bacillus pyocyaneus in one or two epidemics has somewhat more than passing interest. In Cochin-China Calmette found this organism in dysenteric stools, but just how far it was etiologically concerned is somewhat uncertain. That it is capable, however, of inciting such a disease has been abundantly shown by Lartigau. His investigation of the epidemic at Hartwick, New York, in 1898, demonstrated the presence of virulent bacilli, in large numbers, in both the drinking water and stools of the affected individuals. Of the fifteen persons infected eleven recovered and four died.

That the bacillus pyocyaneus does enter the blood, giving rise to a general infection, there can no longer be any doubt. The clinical evolution of the *maladie pyocyanique* in man resembles, in a general way, the other better known forms of septicemia and some of the acute febrile diseases. The general symptoms are those of an infectious disease. Epistaxis has been observed; the spleen is enlarged, and the urine sometimes contains small amounts of albumin and casts. Intestinal disturbances occur with great frequency; diarrhea seems to be the rule. Cutaneous manifestations are very frequent and appear either in the form of bullous eruptions or petechiæ; more rarely is the papular rash observed. The picture thus often simulates typhoid fever. Death occurs in from forty-eight hours to five days or more. The post-mortem examination shows vasomotor disturbances, focal necrosis, hemorrhages, and lesions of the parenchyma of the heart, liver, spleen and kidneys. Intestinal ulcers are common, especially in the less acute cases, and rarely involve more than the mucous membrane. Hemorrhagic enteritis may exist.

ECHOES AND NEWS.

NEW YORK.

The Tarrant Catastrophe.—The frightful explosion of chemicals which shook lower New York City, Monday noon, destroyed a score of lives, completely wrecked two business blocks, and caused scenes of terror never before witnessed in the metropolis, was at first believed to have wiped out of existence two of the oldest and most widely known makers of proprietary medicines in the country, Tarrant & Co., in whose new and substantial seven-story building the accident occurred, and M. J. Breitenbach & Co., whose main office and store-rooms were in the same block. It was soon learned, however, that all of the members of the two firms, and all but one of the employees had almost miraculously escaped with their lives. The details of the terrible occurrence have been made familiar through the daily press, but the following statements as to the condition of the companies will be of interest to the medical fraternity. They were made to the Medical News by Mr. Thomas F. Main, president of the Tarrant Company, and by Mr. M. J. Breitenbach.

Mr. Main said: "In the present confusion we cannot state our plans definitely, though we are straightening out matters as rapidly as circumstances will permit. We expect not only to continue the business, but to begin filling orders regularly within a few weeks. Should we fail to recover any of our books and papers we shall of course be greatly handicapped, but in any event we believe that the delay in resuming shipments will not be protracted." His explanation of the three explosions was: "They were caused by the mixed vapors and gases from the large quantity of chemicals stored in the building, which had been liberated by the fire and the smaller explosion. We had no nitroglycerin."

Mr. Breitenbach said: "We shall resume business at once. We are so situated financially that we do not need to wait for the adjustment of the insurance. That there will be some confusion and delays is unavoidable, but we do not anticipate that they will be serious."

Both companies are occupying temporary quarters at No. 68 Murray Street, New York City, where all correspondence should be addressed until further notice.

Herbalist Practised Medicine.—Cornelius Edisan, a botanist of Richmond Hill, L. I., was held in $500 bail last week in the Lee Avenue police court, Williamsburg, pending a hearing on the charge of practising medicine without a diploma. He is sixty-three years old and well known in Queen's County.

New York's Prison Population.—According to the report of the State Prison Commission, in process of preparation, there has been a net increase of only six prisoners in the State prisons, county penitentiaries, the Elmira Reformatory, and the reformatories for women during the year ending September 30th. The decrease in inmates of prisons and reformatories throughout the State since 1895 is 2615.

Flushing Hospital.—The Flushing Hospital may soon close its doors because of lack of funds to support it. The hospital authorities have issued a statement, showing that it costs $14,000 a year to run the institution. The city gives the hospital $6000 and about $3000 is derived from pay patients. This leaves a balance of $5000 to be raised by subscription. The trustees of the hospital have appealed to the citizens of Flushing to save the hospital.

New York's Death-Rate.—Dr. Henry Dwight Chapin, Chairman of the Committee on Hygiene of the Medical Society of the County of New York, in his annual report, which is just out, among other items, says: "There is happily no special feature to record in reference to the public health of New York City during the past year. The deaths from diarrheal diseases, gastro-enteritis and enteritis may be considered as a fair index in the relation to the general death-rate of the general health and sanitary condition of the community. During June, July, August and September of 1900, 2692 deaths were reported from these causes in the boroughs of Manhattan and The Bronx. This does not represent an unusual number, in comparison with previous years, in spite of the great and continuous heat of the past summer. . . . The general death-rate during 1899 was 19.8 per thousand (it was 20.5 in 1898) and there has been a tendency to a lower death-rate during the past few years. This may be accounted for by a lessening of the virulency of influenza, by better paving of streets, and a more careful oversight of water and milk supply." Dr. Chapin calls attention to what he considers the immediate necessity of taking steps to increase the city's water supply and quotes extensively from the Merchants' Association report on the New York Water Supply. The subject of pure milk is also considered.

PHILADELPHIA.

Anthrax from Fly-Bite.—Michael Bednovick, a tanner of Williamsport, is suffering from anthrax. The disease developed from a fly-bite on the man's arm, the fly presumably having come from diseased hides about the place.

Diphtheria Still Prevalent.—The Haverford College Grammar School has been closed for ten days, although but one case of diphtheria had developed. During last week 119 new cases were reported in the city, one Sunday School being closed to prevent the spread of the disease.

Nurses Graduate.—A class of six nurses was graduated from the training school of the Children's Homeopathic Hospital October 30th.

Death at Advanced Age.—The death at Pittsburg of the oldest man in the State is announced. He was a negro and was proven to be 116 years of age.

Honor for Dr. Lee.—Dr. Benjamin Lee, President of the State Board of Health, was elected president of the American Public Health Association at its recent meeting in Indianapolis.

Filters in Progress.—The residents of Manayunk and Germantown will be the first to get filtered water. Work on five filter-beds, each half an acre in area, is to be begun at once and will be completed in six months. The capacity of this plant will be 6,000,000 gallons daily.

Suspected Foul Play.—Poisoning having been suspected in the case of Dr. Geo. W. Bull who was buried some time ago, the body has been exhumed and the viscera removed for examination. Dr. John Marshall, of the University of Pennsylvania, is to conduct the examinations.

Obituary.—Dr. M. J. Grier died suddenly October 28th of stomach trouble, aged sixty-three years. He was one of the pioneer specialists in nervous diseases and the first physician in this city to apply electricity as a remedy for nerve ailments. Dr. Grier also devoted some time to diseases of the throat and treated many famous singers. He was well advanced in Masonry.

Dr. Geo. A. Muehleck, who died October 24th of typhoid fever, was one of the prominent physicians of the southern section of the city although he was only forty years of age. During the past four years he has been pathologist to St. Agnes' Hospital.

Eucain Anesthesia.—On October 27th Dr. W. B. Van Lennep of the Hahnemann Hospital did an operation upon a case of inguinal hernia under anesthesia induced by injecting eucain into the spinal cord. The patient was a middle-aged white man and he stood the operation well, anesthesia being complete. It has been reported that Dr. Keen's case of October 3d was not successful because the patient afterward died. The death occurred three weeks after the operation, however, and was due to a condition entirely apart from the hernia which was operated on under the spinal anesthesia. Eucainization of the cord, therefore, was in no way responsible for the death of the patient.

Druggists Engage Counsel.—Only five of the many druggists arraigned here for violating the law by not properly displaying their certificates in their stores have paid their fines. The remainder have engaged counsel and will fight the matter in court. A mass meeting is to be held for the purpose of determining on concerted action. In Pittsburg it is claimed that "drug" stores which sell only liquors have been found. In others the detectives employed by the Pharmaceutical Board had prescriptions filled by soda-water dispensers. These actions should of course be stopped, but some of the suits brought against druggists in this city because their certificates were not hanging in the right place seem like persecution.

Honor for Dr. Stengel.—The Board of Managers of the Pennsylvania Hospital, at a meeting Monday afternoon, October 29th, elected Dr. Alfred Stengel visiting physician, to succeed the late Dr. Da Costa. Dr. Stengel is physician to the University and Children's Hospitals, director of the Pepper Laboratory at the University of Pennsylvania, professor of clinical medicine at that institution, editor of the "American Journal of Medical Science" and author of "A Textbook on Pathology." He was graduated from the University in the class of 1889.

CHICAGO.

Diphtheria.—On October 22d the Medical Inspectors closed four rooms at the D. S. Wentworth School, on account of diphtheria among the scholars, and one room at the McCosh School on account of scarlet fever.

Indicted by Federal Jury.—The names of James Armstrong, Thomas Armstrong and John H. Randall, officials of the Metropolitan Medical College, known as a diploma mill, are included in one of the 65 true bills returned by the Federal Grand Jury in the United States District Court.

Public School Medical Inspection.—Last week 2521 pupils were examined by medical inspectors, and of these 184 were found to be suffering from contagious or infectious diseases. In the Board of Health account the other day of the October weekly mortality, attention was called to the fact that during the twenty-five school days since September 7th, the inspectors have examined 9770 ailing children in the public schools, and 694 of these were found to be suffering from contagious diseases liable to spread to other pupils with whom they were in the close contact of school attendance. Among these were sixteen cases of diphtheria, 17 of scarlet fever, 17 of measles, 30 of whooping-cough, 36 of chickenpox, 126 of tonsillitis, 65 of mumps, 13 of purulent sore eyes, 123 of impetigo contagiosa, 145 of pediculosis, 25 of ringworm, 24 of eczema, and 47 of other contagious diseases. These facts and figures establish beyond question the utility of medical inspection as a department of school work and administration.

GENERAL.

Resting Position of Anopheles.—Messrs. Sambon and Low state (*British Med. Jour.*, Oct. 20, 1900) that the generally accepted view, first enunciated by Ross and Austen, that the resting position of Anopheles is sufficient to differentiate this genus from Culex, is not true.

Obituary.—Dr. Moses C. White, eighty-one years old, for years professor in the Yale medical school and for the past fifteen years the Coroner's medical examiner for New Haven, died at midnight, October 25, 1900. He was born in Paris, Oneida County, New York State. He was a graduate of Wesleyan University and of the Yale medical school. He was a missionary in China from 1847 to 1852.

Dr. Alexander H. Johnson, a member of the Board of Health of Newark, N. J., died very suddenly October 26th, at Indianapolis, of heart failure. He was a delegate in attendance at the National Convention of the American Public Health Association.

Sir Henry Ackland, Regius Professor of Medicine in the University of Oxford, died in Oxford October 16th. He was born in 1815 and for sixty years has been closely identified with the life at Oxford.

Medical Students in Italy.—The *Supplemento al Policlinico* of September 15th records that 6648 students were studying medicine during the past academical year in the Italian Universities. These were distributed as follows: Naples, 2209; Turin, 783; Rome, 530; Bologna, 504; Pavia, 496; Genoa, 358; Padua, 309; Palermo, 270; Florence, 260; Pisa, 218; Modena, 152; Catania, 167; Parma, 175; Messina, 128; Sienna, 81; Cagliari, 75; Sassari, 54; Camerrio, 30; Perugia, 29; Ferrara, 15.—*Lancet.*

Dr. Potter Resigns.—Dr. Samuel O. L. Potter has resigned from the Board of Trustees and from the Chair of Theory and Practice of Medicine and Clinical Medicine in the College of Physicians and Surgeons of San Francisco, and has severed his connection with that institution, of which he was one of the incorporators.

Sickness in Philippines.—The report of Surgeon-General Sternberg, U. S. A., says that the present force of the Medical Department consists of 192 officers, which he says is not enough, in view of the large number of coast-defence stations and the troops operating in Cuba, Porto Rico, Hawaii, and the Philippines. The contract surgeons have rendered excellent service, but the Surgeon-General thinks the corps should be increased. Reference is made to the good work the army nurse corps has performed. The medical statistics in the report relate entirely to the calendar year 1899, and nothing is given concerning the statistics for 1900. The Surgeon-General explains the conditions in the Philippines as follows: "The exposures, fatigues, and excitements of a prolonged campaign are responsible for the large sick report and the relatively large death-rate among the troops in the Philippines. However, the opinion is prevalent among our medical officers that in time of peace, and doing only garrison duty, the sick rate of the army in the Philippine Islands would be no higher than it ordinarily is in the Southern United States."

Assistant in Serum Therapeutics.—The United States Civil Service Commission announces that on November 20, 1900, an examination will be held for the position of assistant in serum therapeutics, Biochemic Division, Bureau of Animal Industry, Department of Agriculture. The examination will consist of the subjects mentioned below which will be weighed as follows:

1.	Letter writing (first grade)	10
2.	Elementary general chemistry	20
3.	Serum therapeutics	60
4.	Training and experience in laboratory work	10
	Total	100

Age limit twenty years or over. From the eligibles resulting from this examination it is expected that certification will be made to the position of assistant in serum therapeutics, Biochemic Division, Bureau of Animal Industry, Department of Agriculture, at a salary of $720

per annum, and to other similar vacancies as they shall occur. This examination is open to all citizens of the United States who comply with the requirements and desire to enter the service. All such persons are invited to apply, and applicants will be examined, graded, and certified with entire impartiality and wholly without regard to any consideration save their ability as shown by the grade attained in the examination. Persons who desire to compete should at once apply to the United States Civil Service Commission, Washington, D. C., for application forms 304 and 375, which should be properly executed and promptly forwarded to the Commission.

OBITUARY.

DR. EDWARD R. SQUIBB.

A man whose service to medicine was unique has just died at the age of eighty-one years. Dr. Edward R. Squibb was a graduate of the Jefferson Medical College of Philadelphia, and began his medical career as a surgeon in the United States Navy. Some years later while he was acting as surgeon in charge of the Brooklyn Navy Yard Medical Station, the Civil War broke out, and he was called upon to make use of his knowledge of drugs for the benefit of the Government. His scientific knowledge and skill in the manufacture of pharmaceutical preparations was so great that he saw the need of an excellently equipped laboratory for the perfection of results. As the Government would not supply him with sufficient funds, he fitted up a private laboratory, resigned his government position, and began what has been one of the most valuable life-works that this country has known in the history of medicine, for it was medicine itself of which he was the master. A chemist and a physician he was, with all the keen desire of the true scientist to discover remedies and of the doctor to apply them to human ills. Instead of practising at the bedside with the drugs the names of which he had learned in his medical books, he studied the drugs themselves, chemically, physiologically, therapeutically, and sent them out to his brother practitioners in such form that the whole country, in fact, the profession of the round world, accepted his dictum, and made his name the standard mark for purity and accuracy in pharmaceutical preparations.

Dr. Edward R. Squibb.

His laboratories in Brooklyn have served for nearly half a century as models for all others. So far was he from being the mere manufacturer of medicines, as we to-day understand the term, that he never advertised. His work was recognized as the work of a man of genius for science; and physicians regarded themselves as middle men merely handling what his knowledge and skill had pronounced to be good.

An accident in an explosion in one of his laboratories many years ago nearly caused the loss of his life, at least, it was feared, of his eyesight. He recovered, however, with only a facial disfigurement, which perhaps led him to be more retiring than a man of his fame generally is. His works were widely known through his preparations and his scientific writings, but the man himself was known only to an intimate circle of warm friends. Among these, however, were many physicians who realized that the force and integrity of his character underlay the success of their own work.

He was a man of literary attainments, and of a keen critical ability. He was a member of the New York State Medical Association, the Kings County Medical Association, the Metropolitan Museum of Art, the Philosophical Society of Philadelphia, and many minor societies of kindred character.

For about ten years the active management of his great business has been in the hands of his sons, so that the name so familiar to physicians and pharmacists will, by virtue of the trust implied in it, continue to be worthy of the founder.

Plague at San Francisco.—Cases reported of the 5th and 10th of October have been confirmed by bacterial examination.

Plague from the Philippines.—Government inspectors report that the steamer Bon Lomond, which arrived in London on Friday, October 30th, from the Philippines, had a verified case of plague on board. The victim was removed to a hospital, and the steamer was disinfected.

Dr. Seymour Oppenheimer.—In our report of October 20th of the New York State Medical Association we printed Dr. Oppenheimer's name as Dr. Seymour.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, October 16, 1900.

OPENING OF THE MEDICAL SCHOOLS—INTRODUCTORY ADDRESSES—PROF. CLIFFORD ALLBUTT'S ADDRESS ON ABSTRACTIONS AND FACTS IN MEDICINE—THE SOUTH AFRICAN HOSPITAL COMMISSION—ARREST OF THE OUTBREAK OF PLAGUE IN GLASGOW—THE POLYCLINIC—MR. JONATHAN HUTCHINSON ON THE "ADVANTAGES OF CIRCUMCISION"—RELATIVE IMMUNITY OF JEWS TO SYPHILIS.

With this month of October the medical schools begin a new session. The usual crop of introductory addresses has sprung up all over the country and the medical journals are full of them. As I read these excellent productions, so lofty in tone, so full of good advice to those entering the profession, and, above all, so ambitious in their attempts to tell us what Medicine (with a big M) is, what are its limits, its position in the hierarchy of the sciences, its origin and development in the past, its possibilities in the future, and its services to humanity, some disquieting reflections arise. I have read these philosophical disquisitions year after year for many years, but the problems they discuss seem no nearer a solution. No progress is made, nothing definite is established; we simply move in a circle. Is medicine a science or an art? Is there any truth in the alleged opposition between theory and practice? These are questions which still can be discussed *ad infinitum*. But in the introductory addresses of this year there is one which, by its originality, its boldness of thought, and its philosophical acumen stands out above the rest, and is worthy of attention—the address delivered by Dr. Clifford Allbutt at the Middlesex Hospital. In the application of all the sciences to medicine, that is to say, to a well-meant interference with the most complex and obscure of known machines, there is need, he said, not only of positive knowledge and the scientific habit of mind, but also of a large collection of approximate empirical truths or maxims, for a certain shrewdness and dexterity in the use of such imperfect means and for some insight into men. On the other hand, traditional lore may be handled too reverently; the very provisional nature of practical rules is apt to be forgotten. Every man, as Chateaubriand said, is two men, the man of his time and the man of all time; in some the former, in some the latter character prevails. In the present state of medicine Dr. Allbutt finds a wholesome tendency to the fall of diseases as abstract names and to the rise of the patient. Principles of causation and therapeutics are falling out of fashion and cautious "opportunist" uses of facts and tentative methods are taking their place. The iatromechanical principles of medicine were followed by the iatrochemical, by doctrines of stimulants, of antiphlogistics, of irritability, and so forth. It is to be hoped that physicians will become still more careful in reasoning in abstract terms, for every abstract term is such by virtue of more or less negation; so that a language void of much of its contents is, for purposes of rapidity, employed, just as in traveling by rail a knowledge of the country traversed is sacrificed for speed. There is no such thing as, say, "enteric fever" or "diphtheria;" these are not things but abstract conceptions, the realities being large numbers of individual patients, no two of whom are alike and many of whom are very unlike. If we persist in reasoning in abstract terms only our conceptions become hollow. Thus, in therapeutics volumes of empty stuff are written about tonics, alteratives, and so forth, which is but pasteboard knowledge. The remedy for this easy vice is reiterated and indefatigable reference of every abstract term to its supposed content of facts, and of principles and names of diseases to patients. Dr. Allbutt concluded by advocating the pressing need in all hospitals of clinical laboratories. Mere observation of disease and morbid anatomy have taken medicine almost as far as they can. To keep alive for a year or two a patient who is already in some part half dead is but a poor achievement. Morbid processes must be tracked out to their earliest dynamic initiation. The clinical laboratory of a county hospital should be the center of enlightenment to all the private practitioners of the district.

The South African Hospital Commission held its opening sitting at Kimberley on October 1st. The doctors and members of the hospital staffs agreed that the hospitals in the town were well arranged and equipped and that no complaints had been made. But the evidence of soldiers was directly contradictory. They complained of bad treatment owing to administrative incapacity. At Paardberg, they said, the field hospitals were so badly placed that men lay in pools of water. The camp at Maitland was in a similar position, the men lying in tents full of water, many without blankets, overcoats or oilskins. At Cape Town evidence was taken on October 4th. One of the hospital ships was described as filthy and the milk and food supplies as bad. The civil surgeon of the Tuli hospital complained that the authorities would do nothing. Horses, he said, were allowed to die and rot near the tents, and it was impossible to procure the necessary medicine. Three patients, including one Boer prisoner, died in consequence.

The progress of the plague in Glasgow may be considered completely stayed. No fresh cases have occurred since September 19th. The number of cases in the Belvidere Hospital remains at 21 with 2 still doubtful. Eight more persons who have been in contact with plague-stricken patients have been dismissed from the reception-houses, reducing the number of inmates to 6.

At the Polyclinic Mr. Jonathan Hutchinson de-
